# Additive Spanners and $(\alpha, \beta)$-Spanners* 

Surender Baswana ${ }^{\dagger}$ Telikepalli Kavitha ${ }^{\ddagger}$ Kurt Mehlhorn ${ }^{\S}$ Seth Pettie ${ }^{\S}$

#### Abstract

An $(\alpha, \beta)$-spanner of an unweighted graph $G$ is a subgraph $H$ that distorts distances in $G$ up to a multiplicative factor of $\alpha$ and an additive term $\beta$. It is well known that any graph contains a (multiplicative) $(2 k-1,0)$-spanner of size $O\left(n^{1+1 / k}\right)$ and an (additive) ( 1,2 )-spanner of size $O\left(n^{3 / 2}\right)$. However no other additive spanners are known to exist.

In this paper we develop a couple of new techniques for constructing $(\alpha, \beta)$-spanners. Our first result is an additive ( 1,6 )-spanner of size $O\left(n^{4 / 3}\right)$. The construction algorithm can be understood as an economical agent that assigns costs and values to paths in the graph, purchasing affordable paths and ignoring expensive ones, which are intuitively well-approximated by paths already purchased. We show that this path buying algorithm can be parameterized in different ways to yield other sparseness-distortion tradeoffs. Our second result addresses the problem of which ( $\alpha, \beta$ )-spanners can be computed efficiently, ideally in linear time. We show that for any $k$, a $(k, k-1)$-spanner with size $O\left(k n^{1+1 / k}\right)$ can be found in linear time, and further, that in a distributed network the algorithm terminates in a constant number of rounds. Previous spanner constructions with similar performance had roughly twice the multiplicative distortion.

## 1 Introduction

An $(\alpha, \beta)$-spanner of an undirected graph $G$ is a subgraph $H$ such that for all vertices $u, v$ :

$$
\delta_{H}(u, v) \leq \alpha \cdot \delta_{G}(u, v)+\beta
$$

where $\delta_{G}$ is the distance in graph $G$. In other words, an $(\alpha, \beta)$-spanner guarantees that for pairs of vertices far apart in $G$, their distance in the spanner is stretched by roughly an $\alpha$ factor, which would ideally be close to 1 . We call a ( $1, \beta$ )-spanner an additive $\beta$-spanner. If $\beta=0$ this definition reverts to the usual definition of a multiplicative $\alpha$-spanner $[46,9]$.

Spanners (and related structures) are useful in many contexts. They are the basis of space-efficient routing tables that guarantee nearly shortest routes $[4,53,49,23,24,48]$, schemes for simulating synchronized protocols in unsynchronized networks [47], and parallel and distributed algorithms for computing approximate shortest paths [20,21, 27]. A recent application of spanners is the construction of labeling schemes and distance oracles $[54,14,50,11]$, which are data structures that can report approximately accurate distances in constant time. In all of these applications the quality of the solution ultimately depends on an efficient algorithm for computing a low distortion sparse spanner. The main open problem in this area is to understand the inherent tradeoffs between these three measures of efficiency: distortion ( $\alpha$ and $\beta$ ), sparseness, and construction time. Even ignoring construction time, there are only a handful of cases where the distortion-sparseness tradeoff is fully understood.

[^0]Multiplicative Spanners. The early work on spanners established the basic tradeoff between sparseness and multiplicative distortion. If the spanner size is fixed at $O\left(n^{1+1 / k}\right)$ the multiplicative distortion can be no better than $\Theta(k)$ [46]. We let $n$ and $m$ be the number of vertices and edges in the input graph. Althöfer et al. [9] proposed a greedy algorithm for producing an $(2 k-1)$-spanner whose size is at most $m_{2 k+1}(n)$, where $m_{g}(n)$ is the maximum number of edges in a graph with girth at least $g .{ }^{1}$ Moreover, they observed that $m_{2 k+1}(n)$ is precisely the best possible bound for a $(2 k-1)$-spanner. If one removes any edge from a graph with girth $2 k+1$ the distance between its endpoints jumps from 1 to at least $2 k$. Thus, the only $(2 k-1)$-spanner of such a graph is the graph itself. A trivial upper bound on $m_{2 k+1}(n)$ and $m_{2 k+2}(n)$ is $O\left(n^{1+1 / k}\right)$. It has been conjectured, by Erdős [34] and others that this bound is asymptotically tight, though the conjecture has only been proved for $k=1,2,3$, and 5 ; weaker lower bounds are known for all other $k$; see $[56,54]$. In other words, finding the exact tradeoff between sparseness and multiplicative distortion is at least as hard as proving or disproving the girth conjecture.

The fastest implementations of the Althöfer et al. algorithm run in time $O\left(\min \left\{k n^{2+1 / k}, m n^{1+1 / k}\right\}\right)$ [ 9,51$]$, though there are several more efficient $(2 k-1)$-spanner constructions. Halperin and Zwick [38, 45] compute an $O\left(n^{1+1 / k}\right)$-size $(2 k-1)$-spanner in linear time. However, unlike the algorithm of Althöfer et al., the Halperin-Zwick algorithm only works on unweighted graphs. For weighted graphs Baswana and Sen [12] give a randomized construction of such a spanner with size $O\left(k n^{1+1 / k}\right)$. The Baswana-Sen algorithm has since been derandomized by Roditty et al. [50].

Beyond Purely Multiplicative Distortion. The girth bound exactly characterizes the optimal tradeoff between sparseness and multiplicative distortion but arguments based on girth only apply to adjacent vertices. In unweighted graphs the girth argument could just as easily be interpreted as bounding the additive distortion, or some combination of additive and multiplicative distortion. In particular, if the girth conjecture is true we can only say that an $(\alpha, \beta)$-spanner of size $O\left(n^{1+1 / k}\right)$ has $\alpha+\beta \geq 2 k-1$. It is conceivable that there exist additive $(2 k-2)$-spanners with size $O\left(n^{1+1 / k}\right)$, for any $k$. Before our work, however, only one such additive spanner was known. Aingworth et al. [6] (with followup work in $[25,30,55]$ ) showed that there exist $O\left(n^{3 / 2}\right)$-size additive 2 -spanners. On the lower bound side, Woodruff [57] recently proved that any spanner with size $O\left(k^{-1} n^{1+1 / k}\right)$ cannot do better than an additive distortion of $2 k-2$, independent of whether the girth conjecture is true or not.

The current research trend is to optimize distortion as a function of the distance being approximated, rather than fixate on adjacent vertices and the girth conjecture. Elkin and Peleg [29] showed that the girth bound (on multiplicative distortion) fails to hold even for vertices at distance 2. They gave a construction for $(k-1,2 k-O(1))$-spanners with size $O\left(k n^{1+1 / k}\right)$, with a number of refinements for short distances. They also showed [30] that for any $k \geq 2, \epsilon>0$, there exist $(1+\epsilon, \beta)$-spanners with size $O\left(\beta n^{1+1 / k}\right)$, where $\beta=k^{\log \log k-\log \epsilon}$ is independent of $n$. In other words, the size can be driven close to linear and the multiplicative stretch close to 1 , at the cost of a large additive term in the distortion. Thorup and Zwick [55] give a sparseness-distortion tradeoff that is in some ways stronger than Elkin and Peleg's. Their $(1+\epsilon, \beta)-$ spanners have size $O\left(k n^{1+1 / k}\right)$ and $\beta=O\left(\lceil 1+2 / \epsilon\rceil^{k-2}\right)$, where $\epsilon$ plays no role in the construction and can be chosen as a function of the distance $d$ being approximated. For $\epsilon^{-1}=d^{1 /(k-1)}$, the spanner has additive distortion $O\left(d^{1-1 /(k-1)}+2^{k}\right)$. That is, the multiplicative distortion tends to 1 as the distance increases, whereas the Elkin-Peleg spanners tend to $1+\epsilon$, for an $\epsilon$ chosen a priori. See Figure 1 for a summary of existing spanners constructions.

Our Results. Our first result is that every graph contains an additive 6 -spanner with size $O\left(n^{4 / 3}\right)$ and that such a spanner can be computed efficiently. This result is a far cry from a full spectrum of tradeoffs between sparseness and additive distortion. However, our approach is completely new and is generic enough to be applied in other ways. We view a spanner construction as an economic agent that assigns a cost and value to paths in the graph. Affordable paths are purchased (included in the spanner) and expensive ones ignored. Different cost and value combinations lead to spanners with different properties. Besides constructing a 6 -spanner, our path buying algorithm can be parameterized to find an additive 2 -spanner of size $O\left(n^{3 / 2}\right)$, matching $[6,25,30,55]$, and an additive $\left(n^{1-3 \delta}\right)$-spanners of size $O\left(n^{1+\delta}\right)$, for any constant

## WEIGHTED GRAPHS, MULTIPLICATIVE SPANNERS

| $\alpha$ | Size | Time | Notes |
| :--- | :--- | :--- | :--- |
|  | $\frac{1}{2} n^{1+1 / k}$ | $O\left(m n^{1+1 / k}\right)$ | $[9,7]$ |
| $2 k-1$ | $\frac{1}{2} n^{1+1 / k}$ | $O\left(k n^{2+1 / k}\right)$ | $[51,7]$ |
|  | $O\left(k n^{1+1 / k}\right)$ | $O(k m)($ rand. $)$ | $[12]$ |
|  | $O\left(k n^{1+1 / k}\right)$ | $O(k m)$ | $[50]$ |

UNWEIGHTED GRAPHS, $(\alpha, \beta)$-SPANNERS

| $(\alpha, \beta)$ | Size | Time | Notes |
| :--- | :--- | :--- | :--- |
| $(2 k-1,0)$ | $n^{1+1 / k}$ | $O(m)$ | $[38]$ |
| $(k-1,2 k-O(1))$ | $O\left(k n^{1+1 / k}\right)$ | $O\left(m n^{1-1 / k}\right)$ | $[29]$ |
| $(k, k-1)$ | $O\left(k n^{1+1 / k}\right)$ | $O(k m)$ | new |
| $(1+\epsilon, 4)$ | $O\left(\epsilon^{-1} n^{4 / 3}\right)$ | $O\left(m n^{2 / 3}\right)$ | $[30]$ |
| $(1+\epsilon, \beta)$ | $O\left(\beta n^{1+1 / k}\right)$ | $O\left(n^{2+1 / t}\right)$ | $[30], \beta=\beta(k, \epsilon, t)$ |
| $\left(1+\epsilon, \beta^{\prime}\right)$ | $O\left(\beta^{\prime} n^{1+1 / k}\right)$ | $O\left(m n^{\rho}\right)$ | $[27], \beta^{\prime}=\beta^{\prime}(k, \epsilon, \rho)$ |
| $\left(1+\epsilon, \beta^{\prime \prime}\right)$ | $O\left(k n^{1+1 / k}\right)$ | $O\left(k m n^{1 / k}\right)$ | $[55], \beta^{\prime \prime}=\beta^{\prime \prime}(k, \epsilon)$ |
| $\left(1, n^{1-2 \delta}\right)$ | $O\left(n^{1+\delta}\right)$ | $\operatorname{poly}(n)$ | $[15], \delta=\Theta(1)$ |
| $\left(1, n^{1-3 \delta}\right)$ | $O\left(n^{1+\delta}\right)$ | $\operatorname{poly}(n)$ | new, $\delta=\Theta(1)$ |
| $(1,2)$ | $O\left(n^{3 / 2}\right)$ | $O(m \sqrt{n})$ | $[30,6,55]$ |
| $(1,6)$ | $\tilde{O}\left(n^{3 / 2}\right)$ | $\tilde{O}\left(n^{2}\right)$ | $[25]$ |

Figure 1: State-of-the-art in $(\alpha, \beta)$-spanners. The parameter $k \geq 2$ is always an integer. In the $(1+\epsilon, \beta)$ Spanner of [30], $\beta$ is roughly $k^{\max \{\log \log k-\log \epsilon, \log t, 3\}}$. In [27] it is required that $\rho>1 / 2 k$; the expression for $\beta^{\prime}$ here is quite complicated. In $[55] \beta^{\prime \prime}=2\lceil 1+2 / \epsilon\rceil^{k-2}$; however the construction and spanner are independent of $\epsilon$, meaning it works for all $\epsilon$ simultaneously. Some slower spanner constructions are omitted from the figure.
$\delta \in(0,1 / 3)$. The latter result improves the sparseness of [15] by a polynomial factor. We can also show that graphs with high girth (or, in general, those with few edges on short cycles) contain sparse additive spanners. For example, graphs with girth greater than 4 have $4-, 8$-, and 12 -spanners with sizes on the order of $n^{4 / 3}, n^{5 / 4}$, and $n^{6 / 5}$. Other examples are given in Figure 4 in Section 2.1.

Our second result addresses those sparseness-distortion tradeoffs that can be computed by an efficient algorithm. We show that a $(k, k-1)$-spanner of size $O\left(k n^{1+1 / k}\right)$ can be constructed in $O(k m)$ time. Since the decisions made by the algorithm are very local, it can easily be implemented in modern models of computation. For instance, in the cache-oblivious model [36], the PRAM model [42], or in a synchronized distributed network [45], our algorithm is close to optimal under the relevant measures. Previous spanners with equal or better distortion [29, 30, 27, 55] have construction times of the form $O\left(m n^{\Omega(1)}\right)$ and the result that is most comparable to ours, Elkin and Peleg's $(k-1,2 k-O(1))$-spanner, requires time $O\left(m n^{1-1 / k}\right)$ to compute. If we restrict our attention to linear or near-linear time constructions, all the existing spanners with size $O\left(k n^{1+1 / k}\right)[38,12,50]$ had multiplicative distortion $2 k-1$. Whereas our $(k, k-1)$-spanners can be computed in $O(k)$ rounds in a distributed network, all previous constructions with equal or better distortion required $\Omega\left(n^{\Omega(1)}\right)$ rounds [32].

### 1.1 Related Work

Spanners are part of a large body of work on metric embeddings [41, 40], where one wants a mapping $\phi: S \rightarrow T$ from a given (finite) source metric ${ }^{2}\left(S, \delta_{S}\right)$ to a target metric $\left(T, \delta_{T}\right)$ that does not distort interpoint distances by too much. (Distortion here is usually defined as purely multiplicative distortion.) In our case $\left(S, \delta_{S}\right)$ is some unweighted graph metric and $\phi$ is the identity function; the problem is to find

[^2]a metric $\left(T, \delta_{T}\right)$ corresponding to a sparse subgraph. We only survey metric embeddings where the target metric is some kind of graph.

Roditty, Thorup, and Zwick [49] construct multiplicative spanners for directed graphs under the roundtrip metric, where the distance between two vertices is the length of the shortest cycle (not necessarily simple) that contains both. The sparseness-distortion tradeoffs in [49] are slightly worse than those obtained for undirected graphs. Bollobás et al. [15] and Coppersmith and Elkin [22] studied spanners that preserve, without distortion, the distance between some pairs of vertices. In [15] it is shown that there exist $O\left(n^{1+\delta}\right)$ size spanners that preserve distances greater than $n^{1-\delta}$, and that this tradeoff is optimal. In [22] it is shown that for any set $P$ of pairs of vertices, there is a distance preserver for $P$ with size $O(n+|P| \sqrt{n})$ edges, and that this bound is optimal in some circumstances. In particular, if $|P|=\omega(\sqrt{n})$ then a size of $O(n)$ cannot be guaranteed. Dor, Halperin, and Zwick [25] considered emulators, which may contain both graph edges and additional weighted edges, and observed that there are additive 4-emulators with $O\left(n^{4 / 3}\right)$ edges. Thorup and Zwick [55] generalized this construction to emulators with $O\left(k n^{1+\frac{1}{2^{k}-1}}\right)$ edges and additive distortion $O\left(k d^{1-\frac{1}{k-1}}\right)$, where $d$ is the distance being approximated. One well known application of (multiplicative) spanners is in the construction of approximate distance oracles; see [54] and [14, 50, 11, 43] for more efficient distance oracles.

The sparsest spanner is a tree, but it is impossible to guarantee that a tree spanner has any nontrivial worst case distortion. ${ }^{3}$ A number of weaker notions of distortion have been defined to deal with tree spanners. A probabilistic embedding with distortion $t$ is a distribution over tree metrics such that $\left.\mathbb{E}_{T}\left[\delta_{T}(\phi(u), \phi(v)) / \delta_{S}(u, v)\right]\right\} \leq t$, where it is assumed that $\delta_{T}(\phi(u), \phi(v)) \geq \delta_{S}(u, v)$. Elkin et al. [28] showed that for any graph there is a probabilistic embedding into its spanning trees with distortion $O\left(\log ^{2} n \log \log n\right) .{ }^{4}$ Fakcharoenphol et al. [35] proved that any metric can be probabilistically embedded in a tree metric (not necessarily a spanning tree) with distortion $O(\log n)$. These probabilistic embeddings have surprisingly diverse applications; see $[8,10,35,52,58]$ and the references therein. The distinction between embedding into a spanning subtree vs. any tree metric was explored by Bǎdoiu, Indyk, and Sidiropoulos [16], who showed that the distortion of the best spanning subtree is between $\Omega(\log n / \log \log n)$ and $O(\log n)$ times the distortion of the best tree metric. They also give an algorithm to approximate the best embedding from a given metric into a tree metric. ${ }^{5}$

A number of recent papers look at spanners with $\epsilon$-slack, meaning the stated distortion (a function of $\epsilon$ ) may fail to hold for an $\epsilon$ fraction of the vertex pairs. Such a spanner is gracefully degrading if it has $\epsilon$-slack for all $\epsilon$. Chan, Dinitz, and Gupta [17] give a linear size, gracefully degrading spanner with multiplicative distortion $O\left(\log \epsilon^{-1}\right)$. See $[1,2,3]$ for standard and probabilistic embeddings into tree metrics with $\epsilon$-slack.

For geometric graphs, where the vertices are points in $\mathbb{R}^{d}$, it is known that for any constants $d, \epsilon$, there are efficiently constructible linear size $(1+\epsilon)$-spanners [37, 44]. Geometric graphs fall into a larger class of metrics with constant doubling dimension. ${ }^{6}$ It was recently shown that even these metrics have $(1+\epsilon)$-spanners with size $O(n)$, for constant $\epsilon$ and dimension $d[19,18,39]$.

Organization In Section 2 we introduce the path-buying technique and an algorithm for finding additive 6 -spanners. In Section 2.1 we show how the path-buying algorithm can be parameterized to compute other additive spanners. Section 3 contains our linear time algorithm for constructing $(k, k-1)$-spanners and in Section 3.1 we show how it can easily be adapted to other models of computation. In Section 4 we conclude with some open problems.

## 2 Additive Spanners

Our construction for additive 6 -spanners works in two phases, the first of which involves standard clustering techniques. In phase one we choose a collection of disjoint vertex sets $\mathcal{C}=\left\{C_{1}, C_{2}, \ldots, C_{n^{2 / 3}}\right\}$; each $C_{i}$ is a

[^3]cluster with a center vertex that is adjacent to all other vertices in its cluster. The set $H_{0}$ (which is a subset of our spanner) consists of a radius-one spanning tree of each cluster and all edges that are incident to at least one unclustered vertex. In Section 3 we give two linear time algorithms for constructing $\mathcal{C}$ and $H_{0}$ such that $\left|H_{0}\right| \leq n^{4 / 3}$. Let $\mathcal{C}(v)$ be the cluster containing $v$, if any, and if $Z$ is a subgraph let $\mathcal{C}(Z)$ be the set of clusters that intersect $Z$.

Notice that since $H_{0}$ contains all edges incident to unclustered vertices we can focus our attention on shortest paths whose endpoints are both clustered. The objective of phase two is to show that on any shortest path $P=\left\langle u, \ldots, u^{\prime}\right\rangle$, where both $u$ and $u^{\prime}$ are clustered, there exists a short path $Q$ in the spanner from $u$ to $u^{\prime}$ that passes through some $C^{*} \in \mathcal{C}(P)$. We guarantee, in particular, that the portions of $Q$ from $\mathcal{C}(u) \leadsto C^{*}$ and $C^{*} \leadsto \mathcal{C}\left(u^{\prime}\right)$ are no longer than their counterparts in $P$. Property 2.1 formalizes this idea, and Lemma 2.2 states that any subgraph with this property is an additive 6 -spanner.

Property 2.1 $A$ subgraph $H \supseteq H_{0}$ is happy if for any two clustered vertices $u$, $u^{\prime}$, there exists a shortest path $P=\left\langle u \ldots, u^{\prime}\right\rangle$ in $G$ and a $C^{*} \in \mathcal{C}(P)$ such that:

$$
\delta_{H}\left(\mathcal{C}(v), C^{*}\right) \leq \delta_{P}\left(\mathcal{C}(v), C^{*}\right) \quad \text { for both } v \in\left\{u, u^{\prime}\right\}
$$

Lemma 2.2 Any happy subgraph of $G$ is also an additive 6-spanner of $G$.
Proof: Let $H$ be the happy subgraph, and $u, u^{\prime}, P$, and $C^{*} \in \mathcal{C}(P)$ be as in the statement of Property 2.1; see Figure 2. We can bound the distance from $u$ to $u^{\prime}$ in $H$ as:

Figure 2: The clusters $\mathcal{C}(u), C^{*}$, and $\mathcal{C}\left(u^{\prime}\right)$ indicated by ovals. The shortest inter-cluster paths in $H$ are indicated by dashed curves.

$$
\begin{aligned}
\delta_{H}\left(u, u^{\prime}\right) & \leq \operatorname{diam}_{H}(\mathcal{C}(u))+\delta_{H}\left(\mathcal{C}(u), C^{*}\right)+\operatorname{diam}_{H}\left(C^{*}\right)+\delta_{H}\left(C^{*}, \mathcal{C}\left(u^{\prime}\right)\right)+\operatorname{diam}_{H}\left(\mathcal{C}\left(u^{\prime}\right)\right) \\
& \leq \delta_{P}\left(\mathcal{C}(u), C^{*}\right)+\delta_{P}\left(C^{*}, \mathcal{C}\left(u^{\prime}\right)\right)+6 \\
& \leq \delta_{G}\left(u, u^{\prime}\right)+6
\end{aligned}
$$

where $\operatorname{diam}_{H}(Z)$ represents the maximum distance between vertices in $Z$ in the subgraph $H$. The second inequality follows directly from Property 2.1.

In phase two we find a subgraph $H_{0} \cup P_{1} \cup P_{2} \cup \cdots \cup P_{p}$ where $P_{1}, \ldots, P_{p}$ are paths purchased by the path buying algorithm in Figure 3. The algorithm is parameterized by cost and value functions. It evaluates some shortest path between each pair of vertices and purchases the path if twice its value exceeds its cost. If the path is bought this will influence the cost of value of other paths.

The following cost and value functions give rise to an additive 6 -spanner. In Section 2.1 we show that different costs and values lead to other sparseness-distortion tradeoffs, including a new 2 -spanner of size $O\left(n^{3 / 2}\right)$ that is quite different from previous constructions [6, 25, 30, 55].

$$
\begin{gathered}
\operatorname{value}(P)=\left|\left\{\left\{C, C^{\prime}\right\} \subseteq \mathcal{C}(P): \delta_{P}\left(C, C^{\prime}\right)<\delta_{H}\left(C, C^{\prime}\right)\right\}\right| \\
\operatorname{cost}(P)=|P \backslash H|
\end{gathered}
$$

Note that the cost and value of a path is with respect to a subgraph $H$, which is our spanner under construction. The cost of a path is the number of its edges not already included in the spanner. The value function represents, roughly, how much the inter-cluster distances would be improved if $P$ were included in the spanner.

Our path buying algorithm (Phase 2) is given in Figure 3. It refers to a set $\mathcal{P}$ of shortest paths between all pairs of vertices with the following restrictions. If $P \in \mathcal{P}$ then all subpaths of $P$ are also in $\mathcal{P}$. Furthermore, for every three consecutive vertices $\left\langle u_{1}, u_{2}, u_{3}\right\rangle$ in a path $P \in \mathcal{P}$, if $\mathcal{C}\left(u_{1}\right)=\mathcal{C}\left(u_{3}\right)$, then $u_{2}$ is the center of $\mathcal{C}\left(u_{1}\right)$. This helps to reduce the cost of paths since $\left\langle u_{1}, u_{2}, u_{3}\right\rangle \subseteq H_{0}$.

| $H \leftarrow H_{0}$ | \{edges chosen in clustering\} |
| :--- | :--- |
| For each shortest path $P \in \mathcal{P}$ |  |
| $\quad$ If $2 \cdot \operatorname{value}(P) \geq \operatorname{cost}(P)$ | \{if the path is a bargain \} |
| then $H \leftarrow H \cup P$ | \{then buy it!\} |
| Return $H$ |  |

Figure 3: The path buying algorithm. $\mathcal{P}$ is a set of $\binom{n}{2}$ shortest paths between all pairs of vertices.
The remainder of the proof is structured as follows. In Lemma 2.3 we argue that in the sum of values of paths purchased, the number of times any cluster pair is counted is bounded by a constant. This implies that the sum of values is $O\left(n^{4 / 3}\right)$, since $|\mathcal{C}|=n^{2 / 3}$, and by our criterion for purchasing paths, that the sum of costs is also $O\left(n^{4 / 3}\right)$. In Lemma 2.4 we relate the cost of a path to the number of clusters intersecting it. Finally, and most importantly, Lemma 2.5 shows that if any shortest path is too expensive to be purchased then the existing spanner edges already guarantee a path with additive distortion at most 6 .

In the following lemmas value $(P)$ and $\operatorname{cost}(P)$ represent the value and cost of $P$ at the time it was considered by the path buying algorithm in Figure 3.

Lemma 2.3 Let $H=H_{0} \cup P_{1} \cup P_{2} \cup \cdots \cup P_{p}$, where $P_{i}$ is the ith path bought in the path buying phase. Then $\sum_{i=1}^{p}$ value $\left(P_{i}\right) \leq 5\binom{|\mathcal{C}|}{2}<\frac{5}{2} n^{4 / 3}$.
Proof: Let $H_{i}=H_{0} \cup P_{1} \cup \cdots \cup P_{i}$. For any two clusters $C, C^{\prime} \in \mathcal{C}$ let $P\left(C, C^{\prime}\right)=\left\{P_{j(1)}, P_{j(2)}, \ldots, P_{j(r)}\right\}$ be those purchased paths such that

$$
\delta_{P_{j(k)}}\left(C, C^{\prime}\right)<\delta_{H_{j(k)-1}}\left(C, C^{\prime}\right) \quad \text { for } k \in[1, r] .
$$

By the definition of the value function, $\sum_{i=1}^{p}$ value $\left(P_{i}\right)=\sum_{\left\{C, C^{\prime}\right\} \subseteq \mathcal{C}}\left|P\left(C, C^{\prime}\right)\right|$. Since $P_{j(1)}$ is a shortest path in $G$ we have that: $\delta_{P_{j(1)}}\left(C, C^{\prime}\right) \leq \operatorname{diam}_{G}(C)+\delta_{G}\left(C, C^{\prime}\right)+\operatorname{diam}_{G}\left(C^{\prime}\right) \leq \delta_{G}\left(C, C^{\prime}\right)+4$. This implies that $\left|P\left(C, C^{\prime}\right)\right| \leq 5$ since $\delta_{G}\left(C, C^{\prime}\right) \leq \delta_{P_{j(r)}}\left(C, C^{\prime}\right)<\delta_{P_{j(r-1)}}\left(C, C^{\prime}\right)<\cdots<\delta_{P_{j(1)}}\left(C, C^{\prime}\right) \leq \delta_{G}\left(C, C^{\prime}\right)+4$. That is, after $P_{j(1)}$ is purchased the distance from $C$ to $C^{\prime}$ can only be improved four more times.
Lemma 2.4 If $P \in \mathcal{P}$ then either $|\mathcal{C}(P)|=1$ or there exists a subpath $P^{\prime} \subseteq P$ such that $\mathcal{C}\left(P^{\prime}\right)=\mathcal{C}(P)$ and $\operatorname{cost}\left(P^{\prime}\right) \leq 2\left|\mathcal{C}\left(P^{\prime}\right)\right|-3$.

Proof: Let $P=\left\langle u, \ldots, u^{\prime}\right\rangle$ and $P^{\prime} \subseteq P$ be minimal such that $\mathcal{C}(P)=\mathcal{C}\left(P^{\prime}\right)$. (This means that if the first or last cluster of $P$ has two or three vertices in common with $P$ then only the innermost one appears in $P^{\prime}$.) The only edges in $P^{\prime}$ that might not be in $H \supseteq H_{0}$ are those between clustered vertices. Furthermore, if three consecutive vertices $u_{1}, u_{2}, u_{3}$ belong to the same cluster then $\left\langle u_{1}, u_{2}, u_{3}\right\rangle \subseteq H_{0}$. Thus the total number of inter-cluster edges and intra-cluster edges that are not in $H$ are bounded by $\left|\mathcal{C}\left(P^{\prime}\right)\right|-1$ and $\left|\mathcal{C}\left(P^{\prime}\right)\right|-2$.

Lemma 2.5 The subgraph $H$ returned by the path buying algorithm is happy.
Proof: Let $P=\left\langle u, \ldots, u^{\prime}\right\rangle \in \mathcal{P}$ be the shortest path from $u$ to $u^{\prime}$ in $G$. By the statement of Property 2.1 we can dispense with several trivial cases and assume that $P$ was not purchased in phase two, that both $u$ and $u^{\prime}$ are clustered and that $\mathcal{C}(u) \neq \mathcal{C}\left(u^{\prime}\right)$. Let $P^{\prime} \subseteq P$ be the subpath guaranteed by Lemma 2.4. The case when $P^{\prime}$ is included in $H$ is also trivial. Thus we have the following inequalities:

$$
\begin{equation*}
2 \cdot \operatorname{value}\left(P^{\prime}\right)<\operatorname{cost}\left(P^{\prime}\right) \leq 2 \cdot\left|\mathcal{C}\left(P^{\prime}\right)\right|-3 \tag{1}
\end{equation*}
$$

where the first inequality follows from the fact that $P^{\prime}$ was not included in $H$ and the second from Lemma 2.4. Define $A$ as the set of cluster pairs:

$$
A=\left\{\left\{C_{0}, C_{1}\right\}: \begin{array}{l}
C_{0} \in\left\{\mathcal{C}(u), \mathcal{C}\left(u^{\prime}\right)\right\}, C_{1} \in \mathcal{C}\left(P^{\prime}\right) \backslash\left\{C_{0}\right\} \\
\text { and } \delta_{P^{\prime}}\left(C_{0}, C_{1}\right)<\delta_{H}\left(C_{0}, C_{1}\right)
\end{array}\right\}
$$

The cluster pairs counted in $A$ are also counted in value $\left(P^{\prime}\right)$ so $|A| \leq$ value $\left(P^{\prime}\right)$. By the inequalities of Eqn. 1 value $\left(P^{\prime}\right) \leq\left|\mathcal{C}\left(P^{\prime}\right)\right|-2$. Notice that the maximum number of cluster pairs counted by $A$ is $2\left|\mathcal{C}\left(P^{\prime}\right)\right|-3$. This means that for at least $\left|\mathcal{C}\left(P^{\prime}\right)\right|-1$ of these cluster pairs, their distance in the spanner is no worse than their distance in $P^{\prime}$. By the pigeonhole principle there must be some cluster $C^{*} \in \mathcal{C}\left(P^{\prime}\right)=\mathcal{C}(P)$ satisfying both

$$
\delta_{H}\left(\mathcal{C}(u), C^{*}\right) \leq \delta_{P^{\prime}}\left(\mathcal{C}\left(u^{\prime}\right), C^{*}\right)
$$

and

$$
\delta_{H}\left(C^{*}, \mathcal{C}\left(u^{\prime}\right)\right) \leq \delta_{P^{\prime}}\left(C^{*}, \mathcal{C}\left(u^{\prime}\right)\right)
$$

Since $\mathcal{C}(P)=\mathcal{C}\left(P^{\prime}\right)$ it also follows that $P$ has this property.
Lemma 2.6 If $H$ is the subgraph purchased by the path buying algorithm then $|H|<6 \cdot n^{4 / 3}$.
Proof: One can easily see that $|H|=\left|H_{0}\right|+\sum_{i} \operatorname{cost}\left(P_{i}\right)$. By construction we have $\left|H_{0}\right| \leq n^{4 / 3}$. It follows from Lemma 2.3 that $\sum_{i} \operatorname{cost}\left(P_{i}\right) \leq 2 \cdot \sum_{i} \operatorname{value}\left(P_{i}\right)<5 \cdot n^{4 / 3}$.

Theorem 2.7 There exists an additive 6-spanner of any graph with size $O\left(n^{4 / 3}\right)$.
Proof: Follows from Lemmas 2.2, 2.5, and 2.6.

### 2.1 Parameterizing the Path Buying Algorithm

Our 6-spanner construction can be generalized to larger additive distortion. However, we can only guarantee that a $\beta$-spanner $(\beta>6)$ has $o\left(n^{4 / 3}\right)$ edges if the graph satisfies additional requirements. Let $\Gamma_{k}(G)$ be the number of edges in $G$ that lie on some cycle with length at most $2 k$. Theorem 2.8 generalizes Theorem 2.7 and provides an efficient construction algorithm.

Theorem 2.8 For any graph $G$ and integer parameters $k \geq 1$ and $\ell \in[0, k]$, there exists an additive $(2 k+4 \ell)$-spanner with size $O\left(\Gamma_{k}(G)+n^{1+\frac{1}{k+\ell+1}}\right)$. Furthermore, the spanner can be constructed in time $O\left(m n^{1-\frac{\ell}{k+\ell+1}}\right)$.

Theorem 2.8 says that if the graph is not too far from having girth greater than $2 k$ then we can construct a number of additive spanners with different size-distortion tradeoffs. Notice that when $k=1, \Gamma_{1}(G)=0$ since all graphs have girth at least 3. As special cases, Theorem 2.8 gives 2 - and 6 -spanners with size $O\left(n^{3 / 2}\right)$ and $O\left(n^{4 / 3}\right)$. (This 2-spanner construction is slower and more complicated than earlier ones but it does illustrate the applicability of the path buying algorithm.) Figure 4 lists some of the corollaries of Theorem 2.8 for graphs with girth greater than 4 and greater than 6 .

The spanners provided by Theorem 2.8 are constructed with a path buying algorithm, with the following differences. First, it uses a generalized clustering scheme that produces clusters of two radii: $k$ and $\ell$. Second, it uses a value function that measures how well the spanner under construction approximates the distance between cluster pairs $C, C^{\prime}$, where $C$ has radius $\ell$ and $C^{\prime}$ radius $k$.

Before running the path buying algorithm we compute an appropriate clustering and initial set of edges $H_{k, \ell}$, which plays the same role as $H_{0}$ in our 6 -spanner. This clustering procedure that produces $H_{k, \ell}$ is very similar to the randomized clustering procedure presented later in Section 3, though the analysis of these two schemes is sufficiently different to justify two expositions. We begin by selecting vertex sets $V_{\ell}$ and $V_{k}$ where $V_{\ell}$ is a random sample of $V$ of size $n^{1-\ell \epsilon}$ and $V_{k}$ is a random sample of $V_{\ell}$ of size $n^{1-k \epsilon}$, where $\epsilon$ will be chosen later. We find two clusterings $\mathcal{C}_{\ell}, \mathcal{C}_{k}$, where $\mathcal{C}_{i}$ consists of a set of disjoint subsets of $V$. Each $C \in \mathcal{C}_{i}$ is centered at some vertex in $V_{i}$ and a vertex $v$ is contained in some $C \in \mathcal{C}_{i}$ if and only if $\delta\left(v, V_{i}\right) \leq i$; in particular, the distance from $v$ to the center of its cluster is at most $i . H_{k, \ell}$ consists of a radius- $i$ spanning tree of each $C \in \mathcal{C}_{i}$ and $i \in\{k, \ell\}$, as well as every edge incident to a vertex that does not appear in both clusterings $\mathcal{C}_{\ell}$ and $\mathcal{C}_{k}$. The number of edges contributed by the spanning trees is only $2 n$ so we are mainly concerned with the expected number of the remaining edges.

Lemma 2.9 Given a graph $G$ with $m$ edges, the subgraph $H_{k, \ell}$ can be constructed in $O(m)$ time and $\mathbb{E}\left[\left|H_{k, \ell}\right|\right]=O\left(\Gamma_{k}(G)+n^{1+\epsilon}\right)$.

Figure 4: Additive spanners derived from Theorem 2.8. See [56] for constructions of graphs with girth $>4$ and $>6$, and [54] for references to earlier constructions of high-girth graphs.

Proof: To simplify the analysis we imagine constructing $H_{k, \ell}$ by selecting vertex sets $V=V_{0} \supseteq V_{1} \supseteq \cdots \supseteq$ $V_{k}$, where $V_{i}$ is a random sample of $V_{i-1}$ of size $n^{1-i \epsilon}$. We construct the clusterings $\mathcal{C}_{0}, \ldots, \mathcal{C}_{k}$ iteratively. Let $c \in C \in \mathcal{C}_{i-1}$, where $c \in V_{i-1}$ is the center of a cluster $C$. If $c$ also appears in $V_{i}$ then every vertex incident to $C$ appears in some cluster in $\mathcal{C}_{i}$. In particular, $c$ 's cluster in $\mathcal{C}_{i}$ consists of $C$ and some subset of the vertices incident to $C$ that join $C$. (A vertex may be eligible to join multiple clusters and can choose any one.) Suppose that we decide to include all edges in $H_{k, \ell}$ that have at least one endpoint unclustered in any of $\mathcal{C}_{0}, \ldots, \mathcal{C}_{k}$. Let $v$ be some vertex that has appeared in all the clusterings $\mathcal{C}_{0}, \ldots, \mathcal{C}_{i-1}$ and consider the effect on $v$ of randomly choosing the subset $V_{i}$. Suppose $v$ is incident to $s$ clusters in $\mathcal{C}_{i-1}$, say $C_{1}, \ldots, C_{s}$. The probability that $v$ is included in $\mathcal{C}_{i}$ is at least ${ }^{7} 1-\left(1-n^{-\epsilon}\right)^{s}$. The effect of $v$ not appearing in $\mathcal{C}_{i}$ is to include in $H_{k, \ell}$ all edges incident to $v$, which could be significantly larger than $s$ and $n^{\epsilon}$. Let $\left\{C_{1}, \ldots, C_{s^{\prime}}\right\}$ be those clusters connected to $v$ by at most one edge (this would be exactly one edge, except for the one cluster that actually contains $v$.) Every edge $(v, w)$ connecting $v$ to a cluster $C$ appearing in $\left\{C_{s^{\prime}+1}, \ldots, C_{s}\right\}$ lies on a cycle of length at most $2 i \leq 2 k$ : the one consisting of $(v, w)$, a path from $w$ to $w^{\prime} \in C$ passing through the center of $C$, and the edge $\left(w^{\prime}, v\right)$. Such a $w^{\prime}$ exists because $v$ is connected to $C$ by at least two edges. If $v$ is unclustered in $\mathcal{C}_{i}$ then the contribution of the edges from $v$ to $C_{s^{\prime}+1}, \ldots, C_{s}$ is counted in the $\Gamma_{k}(G)$ term. Excluding these edges, the expected number of edges contributed by $v$ is at most $\left(s^{\prime}-1\right) \cdot \operatorname{Pr}\left[v\right.$ does not appear in $\left.\mathcal{C}_{i}\right] \leq\left(s^{\prime}-1\right)\left(1-n^{-\epsilon}\right)^{s}<n^{\epsilon} .{ }^{8}$

We now turn to the proof of Theorem 2.8.
Proof: (of Theorem 2.8) First notice that the only edges missing from $H_{k, \ell}$ are those with both endpoints present in both clusterings $\mathcal{C}_{\ell}, \mathcal{C}_{k}$, so we can restrict our attention to shortest paths between clustered vertices. Let $\mathcal{C}_{i}(v)$ be the $\mathcal{C}_{i}$ cluster containing $v$ and $\mathcal{C}_{i}(Z)$ be the set of clusters in $\mathcal{C}_{i}$ intersecting the subgraph $Z$. After running the path buying algorithm with appropriate cost and value functions we end up with a spanner $H$ that is happy under a new definition of happiness.

Property 2.10 $A$ subgraph $H$ of $G$ that contains $H_{k, \ell}$ is happy if for any $u, u^{\prime} \in V_{\ell}$, there is a shortest path $P($ w.r.t. $G)$ from $u$ to $u^{\prime}$ and a cluster $C^{*} \in \mathcal{C}_{k}(P)$ such that: $\delta_{H}\left(u, C^{*}\right) \leq \delta_{P}\left(u, C^{*}\right)$ and $\delta_{H}\left(u^{\prime}, C^{*}\right) \leq$ $\delta_{P}\left(u^{\prime}, C^{*}\right)$.

[^4]It follows that any happy subgraph $H$ is also an additive $(2 k+4 \ell)$-spanner. To see this, consider a shortest path between any two vertices $v, v^{\prime}$ and let $u$ and $u^{\prime}$ be the center of the $\mathcal{C}_{\ell}$ clusters containing $v$ and $v^{\prime}$, respectively. Let $P$ be the shortest path between $u$ and $u^{\prime}$. By the happiness of $H$ there exists a cluster $C^{*} \in \mathcal{C}_{k}(P)$ such that

$$
\delta_{H}\left(u, u^{\prime}\right) \leq \delta_{H}\left(u, C^{*}\right)+\operatorname{diam}\left(C^{*}\right)+\delta_{H}\left(C^{*}, u^{\prime}\right) \leq \delta\left(u, u^{\prime}\right)+2 k
$$

Figure 5: The clusters $\mathcal{C}_{\ell}(u), \mathcal{C}_{\ell}\left(u^{\prime}\right)$, and $C^{*} \in \mathcal{C}_{k}$, are indicated by ovals. Dashed curves represent paths in the spanner $H$. The shortest paths in $G$ connecting $v$ to $v^{\prime}$ and $u$ to $u^{\prime}$ are indicated.

Using this bound on the distance from $u$ to $u^{\prime}$ in $H$, we can bound $\delta_{H}\left(v, v^{\prime}\right)$ as:

$$
\delta_{H}\left(v, v^{\prime}\right) \leq \delta_{H}(v, u)+\delta_{H}\left(v^{\prime}, u^{\prime}\right)+\delta_{H}\left(u, u^{\prime}\right) \leq 2 \ell+\delta\left(u, u^{\prime}\right)+2 k \leq \delta\left(v, v^{\prime}\right)+2 k+4 \ell
$$

Let $\mathcal{P}$ be a set of shortest paths between all pairs of vertices. We only consider shortest paths in $\mathcal{P}$ and insist that it satisfy two properties. First, any subpath of a path in $\mathcal{P}$ is also in $\mathcal{P}$. Second, if $\left\langle u_{0}, u_{1}, \ldots, u_{2 k}\right\rangle \in \mathcal{P}$ and $\mathcal{C}_{k}\left(u_{0}\right)=\mathcal{C}_{k}\left(u_{2 k}\right)$, then $u_{k}$ is the center of $\mathcal{C}_{k}\left(u_{0}\right)$ and $\left\langle u_{0}, \ldots, u_{2 k}\right\rangle$ is contained in the spanning tree of $\mathcal{C}_{k}\left(u_{0}\right)$ included in $H_{k, \ell}$. Let $P\left(u, u^{\prime}\right) \in \mathcal{P}$ be the shortest path between $u$ and $u^{\prime}$.

We use the same cost function as before: $\operatorname{cost}(P)=|P \backslash H|$, where $H$ now represents the spanner under construction. However, the value function is only defined on paths connecting vertices in $V_{\ell}$. Letting $P=P\left(u, u^{\prime}\right)$, where $u, u^{\prime} \in V_{\ell}$, we define value $(P)$ as:

$$
\text { value }(P)=\mid\left\{(v, C): v \in\left\{u, u^{\prime}\right\}, C \in \mathcal{C}_{k}(P), \text { and } \delta_{P}(v, C)<\delta_{H}(v, C)\right\} \mid
$$

The path buying algorithm below has a few differences from the 6 -spanner algorithm. We only consider shortest paths between vertices in $V_{\ell}$ and the criterion for purchasing a path $P$ is slightly stronger: $2 k$. value $(P)$ (rather than $2 \cdot \operatorname{value}(P)$ ) must be at least $\operatorname{cost}(P)$.

| $H \leftarrow H_{k, \ell}$ | \{edges chosen in clustering \} |
| :--- | :--- |
| For each $\left\{u, u^{\prime}\right\} \subseteq V_{\ell}$ let $P=P\left(u, u^{\prime}\right)$ |  |
| $\quad$ If $2 k \cdot \operatorname{value}(P) \geq \operatorname{cost}(P)$ | \{if the path is a bargain $\}$ |
| then $H \leftarrow H \cup P$ | \{then buy it!\} |
| Return $H$ |  |

Figure 6: Constructing an additive $(2 k+4 \ell)$-spanner.
Let $P_{1}, \ldots, P_{p}$ be the paths purchased. It follows that the size of $H$ is exactly $\left|H_{k, \ell}\right|$ plus $\sum_{1 \leq i \leq p} \operatorname{cost}\left(P_{i}\right) \leq$ $2 k \sum_{1 \leq i \leq p}$ value $\left(P_{i}\right) \leq 2 \mu k\left|V_{\ell} \times V_{k}\right|=2 \mu k n^{2-(k+\ell) \epsilon}$, where $\mu$ is the maximum number of times that any pair $(v, \bar{C})$, where $v \in V_{\ell}, C \in \mathcal{C}_{k}$ could be counted in $\sum_{i}$ value $\left(P_{i}\right)$. One can see that $\mu=2 k+1$. When $(v, C)$ is first counted, say when $P_{i}$ is purchased, we have $\delta_{P_{i}}(v, C) \leq \delta(v, C)+\operatorname{diam}(C)=\delta(v, C)+2 k$. After
$P_{i}$ is purchased the distance between $v$ and $C$ in $H$ can only be improved $2 k$ more times. Thus, the size of $H$ is $O\left(\Gamma_{k}(G)+n^{1+\epsilon}+k^{2} n^{2-(k+\ell) \epsilon)}\right.$. Setting $n^{\epsilon}=\left(k^{2} n\right)^{1 /(k+\ell+1)}$, the total size is $O\left(\Gamma_{k}(G)+n^{1+1 /(k+\ell+1)}\right)$.

It only remains to show that $H$ is happy and in particular, that if a path $P=P\left(u, u^{\prime}\right)$ is not purchased then $\delta_{H}\left(u, u^{\prime}\right) \leq \delta\left(u, u^{\prime}\right)+2 k$. We first bound $\operatorname{cost}(P)$ then show that if $P$ is not purchased, there must be some $C^{*} \in \mathcal{C}_{k}(P)$ satisfying Property 2.10

Consider any cluster $C \in \mathcal{C}_{k}(P)$ and let $z, z^{\prime}$ be the first and last vertices in $P$ that belong to $C$. An edge is internal to $C$ if it lies on the subpath $\left\langle z, \ldots, z^{\prime}\right\rangle$. (Note that not all vertices between $z$ and $z^{\prime}$ are necessarily in $C$.) It follows from our choice of shortest paths $\mathcal{P}$ that either $\left|\left\langle z, \ldots, z^{\prime}\right\rangle\right| \leq 2 k-1$ or $\left\langle z, \ldots, z^{\prime}\right\rangle \subseteq H_{k, \ell} \subseteq H$. Thus, the total number of internal edges in $P \backslash H$ is at most $(2 k-1)\left|\mathcal{C}_{k}(P)\right|$ and the number of remaining edges in $P \backslash H$ is at most $\left|\mathcal{C}_{k}(P)\right|-1$. In total we have $\operatorname{cost}(P) \leq 2 k\left|\mathcal{C}_{k}(P)\right|-1$. If we fail to purchase $P$ then $2 k \cdot \operatorname{value}(P) \leq \operatorname{cost}(P)-1 \leq 2 k\left|\mathcal{C}_{k}(P)\right|-2$, implying that value $(P) \leq\left|\mathcal{C}_{k}(P)\right|-1$. Since there are $2\left|\mathcal{C}_{k}(P)\right|$ cluster pairs of the form $(v, C)$ where $v \in\left\{u, u^{\prime}\right\}$ and $C \in \mathcal{C}_{k}(P)$, our bound on value $(P)$ implies that for at least one $C^{*} \in \mathcal{C}_{k}(P), \delta_{H}\left(u, C^{*}\right) \leq \delta_{P}\left(u, C^{*}\right)$ and $\delta_{H}\left(u^{\prime}, C^{*}\right) \leq \delta_{P}\left(u^{\prime}, C^{*}\right)$. Therefore $H$ is an additive $(2 k+4 \ell)$-spanner.

We now turn to an efficient construction algorithm. Recall from Lemma 2.9 that $H_{k, \ell}$ can be found in linear time. In the path buying phase it is rather time consuming to maintain the actual distance in $H$ between pairs $(v, C) \in V_{\ell} \times \mathcal{C}_{k}$, which would be required to compute the value function exactly. Instead, we keep an upper bound $\hat{\delta}_{H}(v, C)$, which is the minimum distance between $v$ and $C$ in a path already purchased. We also ignore the cost function and consider the valid upper bound $\operatorname{cost}(P) \leq 2 k\left|\mathcal{C}_{k}(P)\right|-1$. (Clearly these changes do not affect the correctness of the algorithm.) At the beginning of the path buying phase we construct, in $O\left(m\left|\mathcal{C}_{\ell}\right|\right)$ time, a shortest path tree originating at each vertex in $V_{\ell}$. In such a tree a relevant vertex is one in $V_{\ell}$ or one that has at least two $V_{\ell}$ vertices in different subtrees, that is, a branching vertex in the subtree connecting $V_{\ell}$ nodes. For $u \in V_{\ell}$ let $R_{u}$ be the set of relevant vertices in $u$ 's shortest path tree. We consider, in non-decreasing order by length, the shortest paths between pairs $\left(u, u^{\prime}\right)$ where $u \in V_{\ell}$ and $u^{\prime} \in R_{u}$. For a path $P=\left\langle u_{0}, u_{1}, \ldots, u_{q}\right\rangle$, where $u_{0} \in V_{\ell}$, let $\nu\left(u_{0}, u_{q}\right)=\mid\left\{\left(u_{0}, C\right): C \in \mathcal{C}_{k}(P)\right.$ and $\left.\delta_{P}\left(u_{0}, C\right)<\hat{\delta}_{H}\left(u_{0}, C\right)\right\} \mid$. We assume that after $P$ is considered we have computed $\nu\left(u_{0}, u_{i}\right)$ and $\left|\mathcal{C}_{k}\left(\left\langle u_{0}, \ldots, u_{i}\right\rangle\right)\right|$, for all relevant vertices $u_{i} \in R_{u_{0}}$. When we consider an extension of $P$, say $P^{\prime}=\left\langle u_{0}, \ldots, u_{q}, \ldots, u_{q+r}\right\rangle$, where $u_{q+r}$ is the first relevant vertex on the extension, we can easily update $\left|\mathcal{C}_{k}\left(P^{\prime}\right)\right|$ and $\nu\left(u_{0}, u_{q+r}\right)$ in just $O(k+r)$ time. If $u_{q+r} \in V_{\ell}$ then we need to decide whether to purchase $P^{\prime}$. We check if $\nu\left(u_{0}, u_{q+r}\right)+\nu\left(u_{q+r}, u_{0}\right) \geq\left|\mathcal{C}_{k}\left(P^{\prime}\right)\right|$, which serves the same purpose as checking the inequality $2 k \cdot \operatorname{value}\left(P^{\prime}\right) \geq \operatorname{cost}\left(P^{\prime}\right)$. If the inequality holds we buy $P^{\prime}$ and update $\nu\left(u, u^{\prime}\right)$ where $u \in\left\{u_{0}, u_{q+r}\right\}$ and $u^{\prime} \in R_{u}$. This amounts to checking, for each pair $\left(u_{0}, C\right)$ counted in $\nu\left(u_{0}, u_{q+r}\right)$ and each path $P^{\prime \prime}=\left\langle u_{0}, \ldots, u^{\prime}\right\rangle$, whether $\delta_{P^{\prime}}\left(u_{0}, C\right) \leq \delta_{P^{\prime \prime}}\left(u_{0}, C\right)$. If so, the pair $\left(u_{0}, C\right)$ should no longer be counted in $\nu\left(u_{0}, u^{\prime}\right)$, if it was counted there at all. The total time for these updates is $O\left(k \cdot\left|\mathcal{C}_{\ell}\right|^{2} \cdot\left|\mathcal{C}_{k}\right|\right)=O\left(n^{3-\frac{2 \ell k}{k+\ell+1}}\right)$ and the total time for performing breadth first searches is $O\left(m \cdot\left|\mathcal{C}_{\ell}\right|\right)=O\left(m n^{1-\frac{\ell}{k+\ell+1}}\right)$. We can safely assume that $m \geq n^{1+\frac{1}{k+\ell+1}}$; if not we could simply return the original graph as a trivial additive 0 -spanner. For $m$ above this threshold the two time bounds are both $O\left(m n^{1-\frac{\ell}{k+\ell+1}}\right)$.

The first obstacle to improving Theorem 2.8 is dealing with graphs with lots of 3 - and 4 -cycles. It is strange that short cycles should impede the discovery of more additive spanners since high-girth graphs are the most difficult instances when optimizing for multiplicative distortion. The recent lower bounds of Woodruff [57] provide some circumstantial evidence that short cycles really do complicate the problem. His hard instances are actually composed entirely of complete bipartite graphs, where each edge appears on a huge number of 4 -cycles.

Theorem 2.8 generalizes the 6 -spanner construction by considering clusterings with wider radii. Another direction for generalization is to consider more hops between clusters. Theorem 2.11 follows from a small adjustment to the 6 -spanner algorithm.

Theorem 2.11 Every graph on $n$ vertices contains an additive $O\left(n^{1-3 \epsilon}\right)$-spanner with size $O\left(n^{1+\epsilon}\right)$, for any constant $\epsilon \in\left(0, \frac{1}{3}\right)$.

Proof: The algorithm is nearly identical to the 6 -spanner construction. We find a radius- 1 clustering $\mathcal{C}$ containing $n^{1-\epsilon}$ clusters, and let $H_{0}$ contain all edges incident to at least one unclustered vertex and a spanning tree of each cluster. We run the path buying algorithm from Figure 3 using the same cost function
but a different value function:

$$
\operatorname{value}(P)=n^{-1+3 \epsilon} \cdot\left|\left\{\left\{C, C^{\prime}\right\} \subseteq \mathcal{C}(P): \delta_{P}\left(C, C^{\prime}\right)<\delta_{H}\left(C, C^{\prime}\right)\right\}\right|
$$

The rationale for this value function is simple. If there are $n^{1-\epsilon}$ clusters and our desired spanner size is $O\left(n^{1+\epsilon}\right)$, each cluster pair can only afford to be charged the cost of buying $O\left(n^{-1+3 \epsilon}\right)$ edges, that is, a small fraction of a single edge. Let $P$ be some shortest path and $P^{\prime}$ and $P^{\prime \prime}$ be the prefix and suffix of $P$ containing $n^{1-3 \epsilon}$ distinct clusters. If $P$ is not purchased then, by the same reasoning used before, there must be three not necessarily distinct clusters $C^{\prime}, C^{*}, C^{\prime \prime}$ where $C^{\prime} \in \mathcal{C}\left(P^{\prime}\right), C^{\prime \prime} \in \mathcal{C}\left(P^{\prime \prime}\right)$, and $C^{*} \in \mathcal{C}(P)$ such that $\delta_{H}\left(C^{\prime}, C^{*}\right) \leq \delta_{P}\left(C^{\prime}, C^{*}\right)$ and $\delta_{H}\left(C^{\prime \prime}, C^{*}\right) \leq \delta_{P}\left(C^{\prime \prime}, C^{*}\right)$. That is, the subpath of $P$ connecting $C^{\prime}$ to $C^{\prime \prime}$ is approximated by $H$ to within an additive distortion of 6 . To get from the first vertex of $P$ to $C^{\prime}$ and from $C^{\prime \prime}$ to the last vertex of $P$ we use any standard multiplicative $O\left(\epsilon^{-1}\right)$-spanner with size $O\left(n^{1+\epsilon}\right)$. The total additive distortion is therefore $6+O\left(\epsilon^{-1}\left(\operatorname{cost}\left(P^{\prime}\right)+\operatorname{cost}\left(P^{\prime \prime}\right)\right)\right)=O\left(n^{1-3 \epsilon}\right)$. The size of $H_{0}$ and the multiplicative spanner is $O\left(n^{1+\epsilon}\right)$ and the number of edges included by the path buying algorithm is $\sum_{i} \operatorname{cost}\left(P_{i}\right) \leq 2 \sum_{i} \operatorname{value}\left(P_{i}\right)=O\left(n^{-1+3 \epsilon} \cdot\binom{|\mathcal{C}|}{2}\right)=O\left(n^{1+\epsilon}\right)$.

Theorem 2.11 is not particularly impressive, but, again, it illustrates the flexible nature of the path buying technique. The previous best additive spanner with size $O\left(n^{1+\epsilon}\right)$ had distortion roughly $O\left(n^{1-2 \epsilon}\right)$ [15] and was substantially more complicated to construct.

## 3 A Simple ( $k, k-1$ )-Spanner in Linear Time

In this section we will first show how to construct a $(2 k-1,0)$-spanner of size $O\left(k n^{1+1 / k}\right)$ in $O(k m)$ deterministic time. Then we will extend this method to construct a $(k, k-1)$ spanner of size $O\left(k n^{1+1 / k}\right)$ in $O(\mathrm{~km})$ deterministic time.

The input graph is $G=(V, E)$. A cluster is simply a set of vertices and a clustering is a set of disjoint clusters. A vertex is (un)clustered in a clustering $\mathcal{C}$ if it appears (does not appear) in some cluster of $\mathcal{C}$. In a clustering $\mathcal{C}$, for any clustered vertex $u$, denote by $\mathcal{C}(u)$ the cluster of $\mathcal{C}$ that contains $u$. For clusters $C$ and $C^{\prime}$, let $E\left(C, C^{\prime}\right)=\left(C \times C^{\prime}\right) \cap E(G)$ be the set of edges between $C$ and $C^{\prime}$. Let $E(v, C)$ be the set of edges between the vertex $v$ and vertices in $C$. A vertex $v$ is adjacent to a cluster $C$ if $E(v, C) \neq \emptyset$. In a similar manner, two clusters $C$ and $C^{\prime}$ are adjacent to each other if $E\left(C, C^{\prime}\right) \neq \emptyset$.

Our constructions in this section are based on a set of $k+1$ clusterings, $\mathcal{C}_{0}, \mathcal{C}_{1}, \ldots, \mathcal{C}_{k}$, where $\mathcal{C}_{0}=\{\{v\}$ : $v \in V(G)\}, \mathcal{C}_{k}=\emptyset$, and $\left|\mathcal{C}_{i}\right| \leq n^{1-i / k}$. Below, we give two methods for constructing appropriate sequences of clusterings. The edge set of our $(2 k-1)$-spanner $S$ is defined by the following two rules:

Rule R1. For each cluster $C \in \mathcal{C}_{i}$, there exists a tree in $S$ that spans $C$ and has radius ${ }^{9}$ at most $i$.
Rule R2. For each vertex $v$ that is unclustered in $\mathcal{C}_{i}$ and each cluster $C \in \mathcal{C}_{i-1}$ adjacent to $v$, some edge from $E(v, C)$ appears in $S$.

The construction of Theorem 3.1 is slightly weaker than that of [38]; however it is the starting point for our $(k, k-1)$-spanner.

Theorem 3.1 $A(2 k-1)$-spanner of size $O\left(k n^{1+1 / k}\right)$ can be constructed in $O(k m)$ deterministic time.
Proof: We first prove that Rules R1 and R2 give a $(2 k-1)$-spanner; we then prove the size and time bounds. Let $(u, v)$ be an arbitrary edge in the original graph. If $\delta_{S}(u, v) \leq(2 k-1) \delta_{G}(u, v)$ then $S$ is clearly a $(2 k-1)$-spanner. Let $\ell$ be minimum such that either $u$ or $v$ was unclustered in $\mathcal{C}_{\ell}$ and without loss of generality let the unclustered vertex be $u$. By Rule R 2 there must be an edge in $S$ from $u$ to $\mathcal{C}_{\ell-1}(v)$; call this edge $(u, w)$. By Rule R1 there must be a path in $S$ from $w$ to $v$ of length at most $2(\ell-1)$, twice the radius of $\mathcal{C}_{\ell-1}(v)$. Since $\ell \leq k$ it follows immediately that $\delta_{S}(u, v) \leq 2 k-1$.

Given the clustering $\mathcal{C}_{i}$ we show how to compute $\mathcal{C}_{i+1}$ such that the number of edges added to the spanner due to Rules R1 and R2 are at most $n$ and $n^{1+1 / k}$, respectively (This construction is a simplified version of one described by Elkin [26].) Initially $\mathcal{C}_{i+1}=\emptyset$. We define the priority of a cluster $C \in \mathcal{C}_{i}$ to be the

[^5]number of adjacent vertices that are unclustered with respect to $\mathcal{C}_{i+1}$. We repeatedly choose a cluster $C \in \mathcal{C}_{i}$ with maximum priority. If priority $(C) \geq n^{(i+1) / k}$ we add a new cluster to $\mathcal{C}_{i+1}$ consisting of $C$ and all unclustered vertices adjacent to $C$. (If $C$ has radius $i$ then the cluster added to $\mathcal{C}_{i+1}$ clearly has radius $i+1$.) It follows that $\left|\mathcal{C}_{i+1}\right| \leq n^{1-(i+1) / k}$ and that the number of edges included in the spanner due to Rule R2 is $\sum_{C \in \mathcal{C}_{i}}$ priority $(C)$, which is at most $\left|\mathcal{C}_{i}\right|\left(n^{(i+1) / k}-1\right)<n^{1+1 / k}$. The number of edges added due to Rule R 1 is at most the number of clustered vertices in $\mathcal{C}_{i+1}$, i.e. at most $n$. The clustering $\mathcal{C}_{i+1}$ can easily be generated in linear time using a priority queue consisting of $n$ buckets.

The randomized construction of [13] constructs the clusterings in an even simpler manner. Rather than carefully selecting clusters from $\mathcal{C}_{i}$ for inclusion in $\mathcal{C}_{i+1}$, they randomly sample all clusters from $\mathcal{C}_{i}$ with probability $n^{-1 / k}$. The alternative $(2 k-1)$-spanner construction based on this method is given in Figure 7. With this algorithm the expected size of the spanner is $O\left(k n^{1+1 / k}\right)$.

Initially $S=\emptyset$ and $\mathcal{C}_{0}=\{\{v\}: v \in V(G)\}$
For $i$ from 1 to $k$

- Let $\mathcal{C}_{i}$ be sampled from $\mathcal{C}_{i-1}$ with prob. $n^{-1 / k}$ (If $i=k$ let $\mathcal{C}_{k}=\emptyset$ )
- For each vertex $v$ which does not belong to any cluster in $\mathcal{C}_{i}$ do (concurrently):
(R1) If $v$ is adjacent to some $C \in \mathcal{C}_{i}$, add $v$ to $C$ and add some edge of $E(v, C)$ to $S$.
(R2) Otherwise, add to $S$ some edge from $E(v, C)$, for each $C \in \mathcal{C}_{i-1}$ adjacent to $v$.
Return the $(2 k-1)$-spanner $S$

Figure 7: A randomized $(2 k-1)$-spanner construction.
We next improve our $(2 k-1)$-spanner construction to obtain a $(k, k-1)$-spanner. All the edges that we put in the $(2 k-1)$-spanner $S$ are of the form $E(v, C)$. Now let us also add edges of the form $E\left(C, C^{\prime}\right)$, which will consist of edges from clusters of one clustering to clusters of another clustering.

Rule R3. For each $i$ with $0 \leq i \leq k-1$ and for each pair of adjacent clusters $C, C^{\prime}$ with $C \in \mathcal{C}_{i}$ and $C^{\prime} \in \mathcal{C}_{k-1-i}$, some edge from $E\left(C, C^{\prime}\right)$ appears in $S$.

Rule R4. For each $i \geq k / 2$ and each pair of adjacent clusters $C, C^{\prime}$ with $C \in \mathcal{C}_{i}$ and $C^{\prime} \in \mathcal{C}_{i-1}$, some edge from $E\left(C, C^{\prime}\right)$ appears in $S$.

The number of edges included due to Rule R3 is bounded by $n^{1-i / k} n^{1-(k-1-i) / k}=n^{1+1 / k}$, for each $i$. Similarly, at most $n^{1-i / k} n^{1-(i-1) / k}=n^{2-2 i / k+1 / k}$ edges are included due to R4, which is at most $n^{1+1 / k}$ since $i \geq k / 2$. Our entire ( $k, k-1$ )-spanner construction is given in Figure 8. It consists of just those edges included by Rules R1-R4.

> | (R1-2) | Compute a $(2 k-1)$-spanner $S$ with our construction. |
| ---: | :--- |
|  |  |
| (R3) | Add to $S$ one edge from $E\left(C, C^{\prime}\right)$ for each adjacent pair |
|  | $C \in \mathcal{C}_{i}$ and $C^{\prime} \in \mathcal{C}_{k-1-i}$, for $i$ from 0 to $k-1$. |
| (R4) | Add to $S$ one edge from $E\left(C, C^{\prime}\right)$ for each adjacent pair |
|  | $C \in \mathcal{C}_{i}$, and $C^{\prime} \in \mathcal{C}_{i-1}$, for $i$ from $\lceil k / 2\rceil$ to $k-1$. |

Figure 8: A simple linear time algorithm for constructing a $(k, k-1)$-spanner.
Implementing Rules R3 and R4 takes linear time for any fixed $i$. Once it is proved that Rules R1-R4 yield a $(k, k-1)$-spanner we can conclude with the following theorem.

Theorem 3.2 $A(k, k-1)$-spanner of size $O\left(k n^{1+1 / k}\right)$ can be computed in $O(k m)$ deterministic time.
We now show that $S$ is a $(k, k-1)$-spanner. Let $t=\lfloor k / 2\rfloor$. To simplify the exposition we first analyze the case of odd $k$. The case of even $k$ is slightly different and is analyzed later. We need some more definitions. Call a vertex $i$-(un)clustered if it appears (does not appear) in clustering $\mathcal{C}_{i}$. The center of a cluster $C \in \mathcal{C}_{i}$ is a vertex $c \in C$ such that the distance from $c$ to any other vertex in $C$ is at most $i$, the radius of $C$. If $v$ is $i$-clustered let $c_{i}(v)$ be the center of $\mathcal{C}_{i}(v)$.

Let us first indicate our overall proof strategy. In analyzing the stretch of a shortest path $\left\langle u_{0}, u_{1}, \ldots, u_{q}\right\rangle$ we imagine a $(k+1) \times(q+1)$ matrix where the columns correspond to vertices and the rows to clusterings. The $(i, j)$ th matrix entry is marked if $u_{j}$ is $i$-clustered. Clearly $\mathcal{C}_{k}$ 's row is totally unmarked and $\mathcal{C}_{0}$ 's row is totally marked. However the rest of the array can be arbitrary. A particularly easy case is when all of the $u_{i}$ 's are $t$-clustered. We obtain a path from $u_{0}$ to $u_{q}$ via $c_{t}\left(u_{0}\right), c_{t}\left(u_{1}\right), \ldots, c_{t}\left(u_{q}\right)$, which, in the array representation, is represented as a straight line through $\mathcal{C}_{t}$ 's row. In general we have to use clusters with radius larger than $t$, though to establish a multiplicative stretch of $k$ we cannot do this too often. We show, using an inductive argument, that there always exists a spanner path of the proper length that, in the array representation, is composed of a sequence of zig-zags like the one depicted in Figure 10. We achieve an overall multiplicative stretch of $k$ by perfectly balancing detours and shortcuts corresponding to the diagonals above and below $\mathcal{C}_{t}$ 's row.

The proof makes extensive use of the following notations.

$$
f_{i}(v)=\left\{\begin{array}{ll}
v & \text { if } v \text { is } i \text {-unclustered } \\
c_{i}(v) & \text { if } v \text { is } i \text {-clustered }
\end{array} \quad r_{i}(v)= \begin{cases}0 & \text { if } v \text { is } i \text {-unclustered } \\
i & \text { if } v \text { is } i \text {-clustered }\end{cases}\right.
$$

It follows from the definitions that $\delta_{S}\left(v, f_{i}(v)\right) \leq r_{i}(v)$. We will prove the following theorem by induction for any path $\left\langle u_{0}, \ldots, u_{q}\right\rangle$ in $G$.

Theorem 3.3 $\delta_{S}\left(u_{0}, f_{t}\left(u_{i}\right)\right) \leq k i+r_{t}\left(u_{i}\right)$.
Observe that Theorem 3.3 immediately implies that $S$ is a $(k, k-1)$-spanner. If $u_{q}$ is $t$-clustered then there is a path of length $k q+t$ from $u_{0}$ to $c_{t}\left(u_{q}\right)$. Together with the path from $c_{t}\left(u_{q}\right)$ to $u_{q}$ of length at most $t$, we have a path of length $k q+2 t=k q+k-1$ from $u_{0}$ to $u_{q}$ in $S$. If $u_{q}$ is $t$-unclustered then $f_{t}\left(u_{q}\right)=u_{q}$ and $r_{t}\left(u_{q}\right)=0$, implying a path of length $k q$ from $u_{0}$ to $u_{q}$.

We now prove Theorem 3.3. The statement is true for $i=0$ since $\delta_{S}\left(u_{0}, f_{t}\left(u_{0}\right)\right) \leq r_{t}\left(u_{0}\right)$. For the induction step, assume $i>0$ and $\delta_{S}\left(u_{0}, f_{t}\left(u_{s}\right)\right) \leq k s+r_{t}\left(u_{s}\right)$ for all $s<i$. We distinguish cases according to which of $u_{i-1}$ and $u_{i}$ are $t$-clustered. If $u_{i-1}$ is $t$-unclustered then we have $f_{t}\left(u_{i-1}\right)=u_{i-1}$ and $r_{t}\left(u_{i-1}\right)=0$, which means that $\delta_{S}\left(u_{0}, u_{i-1}\right) \leq k(i-1)$. Since $u_{i-1}$ is $t$-unclustered it also follows that $\delta_{S}\left(u_{i-1}, u_{i}\right) \leq 2 t-1$ (see the proof of Theorem 3.1). Hence,

$$
\begin{aligned}
\delta_{S}\left(u_{0}, f_{t}\left(u_{i}\right)\right) & \leq \delta_{S}\left(u_{0}, u_{i-1}\right)+\delta_{S}\left(u_{i-1}, u_{i}\right)+\delta_{S}\left(u_{i}, f_{t}\left(u_{i}\right)\right) \\
& \leq k(i-1)+(2 t-1)+r_{t}\left(u_{i}\right) \\
& \leq k i+r_{t}\left(u_{i}\right)
\end{aligned}
$$

Similarly, if both $u_{i-1}$ and $u_{i}$ are $t$-clustered, then by Rule R3, $S$ contains an edge between $\mathcal{C}_{t}\left(u_{i-1}\right)$ and $\mathcal{C}_{t}\left(u_{i}\right)$ since $t=k-1-t$. So there is a path of length $2 t+1=k$ between $c_{t}\left(u_{i-1}\right)$ and $c_{t}\left(u_{i}\right)$ in $S$. Again we have $\delta_{S}\left(u_{0}, c_{t}\left(u_{i}\right)\right) \leq k i+t$ using the induction hypothesis that $\delta_{S}\left(u_{0}, c_{t}\left(u_{i-1}\right)\right) \leq k(i-1)+t$.

We now come to the final and most interesting case: $u_{i-1}$ is $t$-clustered and $u_{i}$ is $t$-unclustered. Consider the $k \times(q+1)$ table $M$ where rows represent clusterings and columns represent the vertices $u_{0}, \ldots, u_{q}$. The entries of $M$ are 0 or 1 where $M[\ell, j]=0$ means that vertex $u_{j}$ is $\ell$-unclustered and $M[\ell, j]=1$ means that vertex $u_{j}$ is $\ell$-clustered, where $0 \leq \ell \leq k-1$ and $0 \leq j \leq q$. Note that row 0 of $M$ consists of only 1 's since each vertex is a singleton cluster in $\mathcal{C}_{0}$. We are considering the case that $M[t, i-1]=1$ and $M[t, i]=0$.

We want to claim the existence of a vertex $u_{i-j}$ such that $M[t-j, i-j]=1$ while $M[t, i], M[t-1, i-$ $1], \ldots, M[t-j+1, i-j+1]$ are all 0 (as in Figure 9). While following the diagonal sequence of 0 's in the table $M$ starting from the location $M[i, j]$, if we do not reach the starting vertex $u_{0}$, then we have to meet such a $u_{i-j}$ since the bottom row of the table $M$ consists of all 1's. If we reach the zeroth column before finding a 1 , then we have proved our induction step for $i$ because every vertex between $u_{0}$ and $u_{i}$ was $\ell$-unclustered for

Figure 9: The Table $M$. The circled $0-1$ pattern is very useful to us.
some $\ell \leq t$. So without loss of generality, let us assume that such a $u_{i-j}$ exists. Then the following lemma holds.

Lemma 3.4 $\delta_{S}\left(c_{t-j}\left(u_{i-j}\right), u_{i}\right) \leq k j-(t-j)-\sigma(j)$, where $\sigma(j)=\sum_{l=1}^{j} 2 l$.
Proof: We have a path $\left\langle u_{i}, \ldots, u_{i-j+1}, u_{i-j}\right\rangle$ in $G$, where each $u_{i-\ell}$ is $(t-\ell)$-unclustered, for $0 \leq \ell<j$. Suppose $(u, v) \in E$ and $v$ is $(t-\ell)$-unclustered. Then there is a path of length at most $2(t-\ell)-1<k-2 \ell$ between $u$ and $v$ in $S$ (from the proof of Theorem 3.1.) We apply this observation for each consecutive pair of vertices in the path $\left\langle u_{i}, \ldots, u_{i-j+1}, u_{i-j}\right\rangle$. This implies the existence of a path of length at most $\sum_{\ell=1}^{j-1}(k-2 \ell-1)=k(j-1)-\sum_{\ell=1}^{j-1} 2 \ell-(j-1)$ between $u_{i}$ and $u_{i-j+1}$ in $S$. In addition, since $u_{i-j+1}$ is $(t-j)$-unclustered and because it is adjacent to $\mathcal{C}_{t-1-j}\left(u_{j}\right)$, there is an edge from $u_{i-j+1}$ to $\mathcal{C}_{t-1-j}\left(u_{j}\right)$ (by Rule R2). So, there is a path of length at most $1+(t-1-j)=k-2 j-(t-j)$ from $u_{i-j+1}$ to $c_{t-1-j}\left(u_{i-j}\right)$. Hence, there is a path of length at most $k j-(t-j)-(j-1)-\sum_{\ell=1}^{j} 2 \ell$ between $u_{i}$ and $c_{t-1-j}\left(u_{i-j}\right)$ in $S$.

Note that the above lemma says that we have a path from $u_{i}$ to $c_{t-j}\left(u_{i-j}\right)$ that is shorter, by $t-j+\sigma(j)$, than we were already prepared to pay for. We will use these savings to pay for a path from $u_{0}$ to $c_{t-j}\left(u_{i-j}\right)$ that is longer than we could ordinarily afford. A remarkable feature of our analysis is that we amortize over paths of length $\Omega\left(k^{2}\right)$ yet the spanner construction itself never makes decisions within this wide a horizon.

We now need to exhibit a path in $S$ from $c_{t-j}\left(u_{i-j}\right)$ to $u_{0}$ whose length is no more than $k(i-j)+(t-$ $j)+\sigma(j)$. We will first show a path in $S$ from $c_{t-j}\left(u_{i-j}\right)$ to $f_{t+j}\left(u_{i-j-1}\right)$, using Rules R1-3, then show another path from $f_{t+j}\left(u_{i-j-1}\right)$ to $f_{t}\left(u_{i-2 j-1}\right)$, which uses Rules R1-2 and R4 (see Figure 10). Finally, we invoke the induction hypothesis for $i-2 j-1$.

Lemma 3.5 Let $(u, v) \in E$ be an edge and suppose that $v$ is $(t-j)$-clustered. Then

$$
\delta_{S}\left(f_{t+j}(u), c_{t-j}(v)\right) \leq k+2 j+(t-j)-r_{t+j}(u)
$$

Proof: If $u$ is $(t+j)$-unclustered then there is a path of length at most $2(t+j)-1<k+2 j$ in $S$ from $u$ to $v$. Since there is a path of length $\leq t-j$ from $v$ to $c_{t-j}(v)$ in $S$, there is a path of length at most $k+2 j+(t-j)$ from $u$ to $c_{t-j}(v)$ in $S$, which is exactly what we want since $f_{t+j}(u)=u$ and $r_{t+j}(u)=0$.

The other case is when $u$ is $(t+j)$-clustered. By Rule R3 there is an edge in $S$ between $\mathcal{C}_{t+j}(u)$ and $\mathcal{C}_{t-j}(v)$. This gives us a path of length $1+(t+j)+(t-j)=k$ between $c_{t+j}(u)$ and $c_{t-j}(v)$. This is again exactly what we want since $2 j+(t-j)-r_{t+j}(u)=0$.

Lemma 3.6 Let $\left\langle u_{s}, \ldots, u_{s+j}\right\rangle$ be a path in the graph $G$. Then

$$
\delta_{S}\left(f_{t}\left(u_{s}\right), f_{t+j}\left(u_{s+j}\right)\right) \leq k j+r_{t+j}\left(u_{s+j}\right)-r_{t}\left(u_{s}\right)+\sigma(j-1)
$$

where as defined earlier, $\sigma(j-1)=\sum_{l=1}^{j-1} 2 l$.

Each $x$ is a $0 / 1$

Figure 10: The sub-paths that make up our path from $u_{i}$ to $u_{0}$ in $S$.

Proof: Consider two successive vertices $u_{s+\ell-1}$ and $u_{s+\ell}$ in the above path. Depending upon whether $u_{s+\ell-1}$ and $u_{s+\ell}$ appear in clusterings $\mathcal{C}_{t+\ell-1}$ and $\mathcal{C}_{t+\ell}$, respectively, we have four cases: both are unclustered, both are clustered, $u_{s+\ell-1}$ is clustered but $u_{s+\ell}$ is not and vice-versa. It is simple to check that in all the four cases $\delta_{S}\left(f_{t+\ell-1}\left(u_{s+\ell-1}\right), f_{t+\ell}\left(u_{s+\ell}\right)\right) \leq k+r_{t+\ell}\left(u_{s+\ell}\right)-r_{t+\ell-1}\left(u_{s+\ell-1}\right)+2(\ell-1)$. So, summing this over all pairs $\left(u_{s+\ell-1}, u_{s+\ell}\right)$, as $\ell$ ranges from 1 to $j$, we get that $\delta_{S}\left(f_{t}\left(u_{s}\right), f_{t+j}\left(u_{s+j}\right)\right) \leq k j+r_{t+j}\left(u_{s+j}\right)-r_{t}\left(u_{s}\right)+$ $\sum_{\ell=1}^{j} 2(\ell-1)$.

Using Lemmas 3.5 and 3.6 , it is now easy to complete our proof. We have the desired vertex $u_{i-j}$. Lemma 3.4 provides us with a path of length at most $k j-(t-j)-\sigma(j)$ between $u_{i}$ and $c_{t-j}\left(u_{i-j}\right)$ in $S$, Lemma 3.5 provides us with a path of length at most $k+2 j+(t-j)-r_{t+j}(u)$ between $c_{t-j}\left(u_{i-j}\right)$ and $f_{t+j}\left(u_{i-j-1}\right)$ in $S$, and Lemma 3.6 with $s=i-2 j-1$ provides us with a path of length at most $k j+r_{t+j}\left(u_{i-j-1}\right)-r_{t}\left(u_{s}\right)+\sigma(j-1)$ from $f_{t}\left(u_{s}\right)$ to $f_{t+j}\left(u_{i-j-1}\right)$. In summary:

$$
\begin{aligned}
\delta_{S}\left(c_{t-j}\left(u_{i-j}\right), u_{i}\right) & \leq k j-(t-j)-\sigma(j) \\
\delta_{S}\left(f_{t+j}\left(u_{i-j-1}\right), c_{t-j}\left(u_{i-j}\right)\right) & \leq k+2 j+(t-j)-r_{t+j}\left(u_{i-j-1}\right) \\
\delta_{S}\left(f_{t}\left(u_{i-2 j-1}\right), f_{t+j}\left(u_{i-j-1}\right)\right) & \leq k j+r_{t+j}\left(u_{i-j-1}\right)-r_{t}\left(u_{i-2 j-1}\right)+\sigma(j-1) .
\end{aligned}
$$

So, adding the above 3 inequalities and using $\sigma(j-1)+2 j=\sigma(j)$, we get that there is a path of length at most $k(2 j+1)-r_{t}\left(u_{s}\right)$ from $f_{t}\left(u_{s}\right)$ to $u_{i}$ where $s=i-2 j-1$. We know from the induction hypothesis that there is a path of length at most $k s+r_{t}\left(u_{s}\right)$ from $u_{0}$ to $f_{t}\left(u_{s}\right)$. So, we have a path of length at most $k i$ from $u_{0}$ to $u_{i}$, which proves our induction step because we are in the case where $f_{t}\left(u_{i}\right)=u_{i}$ and $r_{t}\left(u_{i}\right)=0$.

Note that we have made the assumption that $i-2 j-1 \geq 0$, which is always true when $i \geq k$. However, we did not explicitly consider the possibility that $u_{i-j}=u_{0}$, or that $u_{i-j-1}=u_{0}$, or that before we came to $u_{i-2 j-1}$ we met the starting vertex. It is easy to check that these three cases can be handled as corollaries to Lemmas 3.4, 3.5, and 3.6, respectively. This finishes the proof of Theorem 3.3 for the case when $k$ is odd.

The case when $k$ is even. Let us now consider the case of even $k$. In this case, $t=\lfloor k / 2\rfloor$ implies $k=2 t$. Rule R3 now connects clusters of $\mathcal{C}_{t}$ with adjacent clusters of $\mathcal{C}_{k-1-t}$, which is $\mathcal{C}_{t-1}$. So, if we consider a path $\left\langle u_{0}, \ldots, u_{q}\right\rangle$ in $G$ and each $u_{i}$ is $t$-clustered, then this does not translate to a path of length at most $k q+k-1$ between $u_{0}$ and $u_{q}$ in $S$, when $k$ is even. If every $u_{2 i}$ is $(t-1)$-clustered and every $u_{2 i-1}$ is $t$-clustered, then $\delta_{S}\left(f_{t-1}\left(u_{2 i}\right), f_{t}\left(u_{2 i-1}\right)\right) \leq k$ and $\delta_{S}\left(f_{t-1}\left(u_{2 i}\right), f_{t}\left(u_{2 i+1}\right)\right) \leq k$. Combining these paths, we get a path of length at most $k q+k-1$ from $u_{0}$ to $u_{q}$.

Coming back to the general case, our approach is the same as when $k$ is odd. But there we had used level $t$ as a reference and proved that $\delta_{S}\left(u_{0}, f_{t}\left(u_{i}\right)\right) \leq k i+r_{t}\left(u_{q}\right)$. Now we need to alternate between $t$ and $t-1$ as our reference for odd and even indexed vertices, respectively, in the path $\left\langle u_{0}, \ldots, u_{q}\right\rangle$. So we introduce
some more notations:

$$
h(i)=\left\{\begin{array}{ll}
t-1 & \text { if } i \text { is even } \\
t & \text { if } i \text { is odd }
\end{array} \quad r^{\prime}(i)= \begin{cases}t-1 & \text { if } u_{i} \text { is } h(i) \text {-clustered } \\
0 & \text { if } u_{i} \text { is } h(i) \text {-unclustered }\end{cases}\right.
$$

We will show the following theorem here.
Theorem 3.7 $\delta_{S}\left(u_{0}, f_{h(i)}\left(u_{i}\right)\right) \leq k i+r^{\prime}(i)$.
This theorem immediately implies that $S$ is a $(k, k-1)$-spanner because if $u_{q}$ is $h(q)$-unclustered, then there is a path of length at most $k q$ from $u_{0}$ to $u_{q}$. If $u_{q}$ is $h(q)$-clustered, there is a path of length $k q+t-1$ from $u_{0}$ to $c_{h(q)}\left(u_{q}\right)$ and there is a path of length at most $t$ from $c_{h(q)}\left(u_{q}\right)$ to $u_{q}$. So, we have a path of length at most $k q+t-1+t=k q+k-1$ from $u_{0}$ to $u_{q}$.

Our proof will follow the same strategy as the proof of Theorem 3.3. We will prove the above theorem by induction. Since $h(0)=t-1$, the base case holds. We assume that $\delta_{S}\left(u_{0}, f_{h(s)}\left(u_{s}\right)\right) \leq k s+r^{\prime}(s)$ for all $s<i$ and we will prove the induction step for $i$. If $u_{i-1}$ is $h(i-1)$-unclustered, then we have a path of length at most $2 h(i-1)-1 \leq 2 t-1$ from $u_{i-1}$ to $u_{i}$ and there is a path of length at most $r^{\prime}(i)+1$ from $u_{i}$ to $f_{h(i)}\left(u_{i}\right)$. Hence, using the induction hypothesis for $u_{i-1}$ and combining it with the above paths to $u_{i}$ and $f_{h(i)}\left(u_{i}\right)$, we get that there is a path of length at most $k(i-1)+2 t-1+r^{\prime}(i)+1=k i+r^{\prime}(i)$ from $u_{0}$ to $u_{i}$.

Similarly, if $u_{i-1}$ is $h(i-1)$-clustered and $u_{i}$ is $h(i)$-clustered, since $h(i-1)+h(i)=k-1$, we would have put an edge between $\mathcal{C}_{h(i-1)}\left(u_{i-1}\right)$ and $\mathcal{C}_{h(i)}\left(u_{i}\right)$ (by Rule R3). This gives us a path of length at most $h(i-1)+1+h(i)=2 t=k$ between $c_{h(i-1)}\left(u_{i-1}\right)$ and $c_{h(i)}\left(u_{i}\right)$. So, using this path along with the induction hypothesis, we get a path of length at most $k i+t-1$ from $u_{0}$ to $c_{h(i)}\left(u_{i}\right)$.

The non-trivial case is again when $u_{i-1}$ is $h(i-1)$-clustered and $u_{i}$ is $h(i)$-unclustered. Here, there is one easy sub-case. If $h(i)=t$, then in the table $M$ (refer Figure 9), we have the desired $1-0$ pattern right at our doorstep. We have $M[t-1, i-1]=1$ and $M[t, i]=0$. So, this gives us a path of length at most $1+t-1$ from $u_{i}$ to $c_{t-1}\left(u_{i-1}\right)$. And the induction hypothesis tells us that there is a path of length at most $k(i-1)+t-1$ from $u_{0}$ to $c_{t-1}\left(u_{i-1}\right)$. Hence there is a path of length at most $k i$ from $u_{0}$ to $u_{i}$, which is what we want to show.

So, the only case left is when $u_{i-1}$ is $h(i-1)$-clustered and $u_{i}$ is $h(i)$-unclustered and $h(i)=t-1$. Then as in the proof of Theorem 3.3, we want to claim that there exists a vertex $u_{i-j}$ such that, in the table $M$, $M[t-1-j, i-j]=1$ while $M[t-1, i], M[t-2, i-1], \ldots, M[t-j, i-j+1]$ are all 0 . Either such a $u_{i-j}$ exists (since the bottom row of the table $M$ consists of all 1 's) or while following the diagonal path of 0 's in the table $M$, we reach the starting vertex $u_{0}$. In the latter case, we have proved our induction step for $i$, because every vertex $u_{i-\ell}$ in $\left\langle u_{0}, \ldots, u_{i}\right\rangle$ is $(t-1-\ell)$-unclustered. Then, there is a path of length $\leq 2 t-1<k$ in $S$ between every consecutive pair of vertices in $\left\langle u_{0}, \ldots, u_{i}\right\rangle$. So, without loss of generality, let us assume that such a $u_{i-j}$ exists.

We need lemmas which are analogous to Lemma 3.4, Lemma 3.5, and Lemma 3.6. The proofs of Lemma 3.8 and Lemma 3.9 are identical to those of Lemma 3.4 and Lemma 3.5 respectively.

Lemma $3.8 \delta_{S}\left(c_{t-1-j}\left(u_{i-j}\right), u_{i}\right) \leq k j-(t-j)-\sigma(j)-(j-1)$, where $\sigma(j)=\sum_{l=1}^{j} 2 l$.
Lemma 3.9 Suppose $(u, v) \in E$. Suppose $v$ is $(t-1-j)$-clustered. Then

$$
\delta_{S}\left(f_{t+j}(u), c_{t-1-j}(v)\right) \leq k+2 j+(t-j)-r_{t+j}(u)
$$

Lemma 3.10 Let $\left\langle u_{s}, \ldots, u_{s+j}\right\rangle$ be a path in the graph $G$. Then

$$
\delta_{S}\left(f_{t}\left(u_{s}\right), f_{t+j}\left(u_{s+j}\right)\right) \leq k j+j+r_{t+j}\left(u_{s+j}\right)-r_{t}\left(u_{s}\right)+\sigma(j-1)
$$

If $u_{s}$ is $t$-unclustered, then

$$
\delta_{S}\left(u_{s}, f_{t+j}\left(u_{s+j}\right)\right) \leq k j+j-1+r_{t+j}\left(u_{s+j}\right)+\sigma(j-1)
$$

where as defined earlier, $\sigma(j-1)=\sum_{l=1}^{j-1} 2 l$.

Proof: $\left\langle u_{s}, \ldots, u_{s+j}\right\rangle$ is a path in $G$. Consider two successive vertices $u_{s+\ell-1}$ and $u_{s+\ell}$ in the above path. Depending upon how $u_{s+\ell-1}$ and $u_{s+\ell}$ appear in clusterings $\mathcal{C}_{t+\ell-1}$ and $\mathcal{C}_{t+\ell}$ respectively, we have four cases: both are unclustered, both are clustered, $u_{s+\ell-1}$ is clustered but $u_{s+\ell}$ is not and vice-versa. It is simple to check that in all the four cases $\delta_{S}\left(f_{t+\ell-1}\left(u_{s+\ell-1}\right), f_{t+\ell}\left(u_{s+\ell}\right)\right) \leq k+1+r_{t+\ell}\left(u_{s+\ell}\right)-r_{t+\ell-1}\left(u_{s+\ell-1}\right)+2(\ell-1)$. So, summing this over all pairs $\left(u_{s+\ell-1}, u_{s+\ell}\right)$, as $\ell$ ranges from 1 to $j$, we get that $\delta_{S}\left(f_{t}\left(u_{s}\right), f_{t+j}\left(u_{s+j}\right)\right) \leq$ $k j+j+r_{t+j}\left(u_{s+j}\right)-r_{t}\left(u_{s}\right)+\sum_{\ell=1}^{j} 2(\ell-1)$.

If $u_{s}$ is $t$-unclustered, then there is a path of length at most $2 t-1$ from $u_{s}$ to $u_{s+1}$ and a path of length at most $r_{t+1}\left(u_{s+1}\right)$ from $u_{s+1}$ to $f_{t+1}\left(u_{s+1}\right)$, which gives us an upper bound of $k+r_{t+1}\left(u_{s+1}\right)$ for $\delta_{S}\left(u_{s}, f_{t+1}\left(u_{s+1}\right)\right.$ instead of $k+1+r_{t+1}\left(u_{s+1}\right)$ for the $\left\langle u_{s}, u_{s+1}\right\rangle$ path. This path, when combined with the $\left\langle u_{s+1}, \ldots, u_{s+j}\right\rangle$ path obtained from the previous paragraph shows that $\delta_{S}\left(f_{t}\left(u_{s}\right), f_{t+j}\left(u_{s+j}\right)\right) \leq$ $k j+j-1+r_{t+j}\left(u_{s+j}\right)+\sum_{\ell=1}^{j} 2(\ell-1)$.

So, as in the proof of Theorem 3.3, we use the path given by Lemma 3.8 to go from $u_{i}$ to $c_{t-1-j}\left(u_{i-j}\right)$ and then use the path given by Lemma 3.9 to go from $c_{t-1-j}\left(u_{i-j}\right)$ to $f_{t+j}\left(u_{i-j-1}\right)$ and then use the path given by Lemma 3.10 to go from $f_{t+j}\left(u_{i-j-1}\right)$ to $f_{t}\left(u_{i-2 j-1}\right)$. So, if we can show that $h(i-2 j-1)=t$, then we can use the induction hypothesis to claim that there is a path of length at most $k(i-2 j-1)+r^{\prime}(i-2 j-1)$ from $u_{0}$ to $f_{t}\left(u_{i-2 j-1}\right)$.

Lemma $3.11 h(i-2 j-1)=t$.
Proof: This is simple to show. Since $h(\ell)=t$ if and only if $\ell$ is odd, we need to show that $i-2 j-1$ is odd. We know that $i$ must be even since $h(i)=t-1$. Hence, $i-2 j-1$ is odd.

So, we can use the induction hypothesis that there is a path of length $\leq k(i-2 j-1)+r^{\prime}(i-2 j-1)$ from $u_{0}$ to $f_{t}\left(u_{i-2 j-1}\right)$. Suppose $u_{i-2 j-1}$ is $h(i-2 j-1)$-clustered. Then $r^{\prime}(i-2 j-1)=t-1$. And we get a path from $u_{0}$ to $u_{i}$ in $S$ of length at most $k(i-2 j-1)+t-1+k j+j+r_{t+j}\left(u_{i-j-1}\right)-t+\sigma(j-1)+k+2 j+$ $(t-j)-r_{t+j}\left(u_{i-j-1}\right)+k j-(t-j)-\sigma(j)-(j-1)=k i$. If $u_{i-2 j-1}$ is $t$-unclustered, then we use the second part of Lemma 3.10 to upper bound the $\left\langle u_{i-2 j-1}, \ldots, u_{i-j-1}\right\rangle$ path. So, there is a path of length at most $k(i-2 j-1)+k j+j-1+r_{t+j}\left(u_{i-j-1}\right)+\sigma(j-1)+k+2 j+(t-j)-r_{t+j}\left(u_{i-j-1}\right)+k j-(t-j)-\sigma(j)-(j-1)=k i$ between $u_{0}$ and $u_{i}$ in $S$. This proves our induction step.

Again, the three cases that $u_{i-j}=u_{0}$ or $u_{i-j-1}=u_{0}$ or before we came to $u_{i-2 j-1}$, we see the starting vertex, can be handled as corollaries to Lemmas 3.8, 3.9, and 3.10 respectively. This finishes the proof of Theorem 3.7 for the case when $k$ is even. Recall that Theorem 3.3 which shows the correctness for odd $k$ was already proved. Thus Theorem 3.2 is completely proved.

### 3.1 Implementation in other models of computations

Our algorithm (Figure 8) for ( $k, k-1$ )-spanners can be adapted quite easily to other models of computation. The complexity of each of these algorithms is close to optimal under relevant measures.

- In the external memory model [5] and the cache oblivious model [36], a ( $k, k-1$ )-spanner of $O\left(k n^{1+1 / k}\right)$ size can be computed using the same number of $I / O$ operations as that of sorting $k m$ items. Sorting is one of the most primitive tasks in both models and optimal algorithms are known.
- In the CRCW PRAM model [42], a $(k, k-1)$-spanner of expected size $O\left(k n^{1+1 / k}\right)$ can be computed in $O\left(k \log ^{*} n\right)$ time and $O(k m)$ work. The algorithm employs primitive parallel subroutines like computing the smallest element, semisorting, and multiset hashing.
- In the synchronous distributed model [45], a ( $k, k-1$ )-spanner of expected $O\left(k n^{1+1 / k}\right)$ size can be computed in $O(k)$ rounds with total message volume $O\left(k^{2} m\right)$.

In order to convey to the reader the ease with which the algorithm is adapted in these models, we provide below the execution of the $(k, k-1)$-spanner construction in distributed environment. Adaptation of the algorithm in the external-memory and CRCW PRAM environment as mentioned above is similar to the adaptation of $(2 k-1)$-spanner algorithm of Baswana and Sen [12] in these models.

### 3.2 Distributed algorithm for ( $k, k-1$ )-spanner

Rules R3 and R4 of our algorithm (Figure 8) can be executed in $O(k)$ rounds of communication in a distributed network, and, using the randomized algorithm from Figure 7, Rules R1 and R2 can also be executed in $O(k)$ rounds. The main result in this section is Theorem 3.12. Before we prove it, let us elaborate a little on our model of distributed computation. In a synchronized distributed network the nodes of the network solve a problem by exchanging messages in discrete rounds. In each round one message may be sent across each link in each direction. We are interested in three measures: the number of rounds, the maximum length of any message sent (measured in units of $O(\log n)$ bits) and the total length of all messages sent. Clearly any protocol requiring $R$ rounds, maximum message length $L$ and total volume $V$ can be converted to one with parameters $R L / U, U$, and $V$, for any any $U \geq 1$. That is, Theorem 3.12 can be adapted to any synchronized network with a fixed maximum message length.

Theorem 3.12 In a synchronized distributed network $G$, $a(k, k-1)$-spanner of $G$ whose expected size is $O\left(k n^{1+1 / k}\right)$, can be constructed in $O(k)$ rounds of communication. The total message volume is $O\left(k^{2} m\right)$ and the maximum message length is $O\left(n^{1 / 2+1 / 2 k}\right)$.

Proof: We compute the clusters $\mathcal{C}_{0}, \mathcal{C}_{1}, \ldots, \mathcal{C}_{k}=\emptyset$ using the randomized algorithm from Figure 7. Each vertex is the center of its cluster in $\mathcal{C}_{0}=\{\{v\}: v \in V(G)\}$. With probability $n^{-1 / k}$ each center in $\mathcal{C}_{i}$ declares itself to also be a center in $\mathcal{C}_{i+1}$. These random choices are made before the first round of communication.

After $\mathcal{C}_{i}$ is computed, every vertex tells its neighbors whether it is clustered in $\mathcal{C}_{i}$ and if it is, the identity of its center in $\mathcal{C}_{i}$ and the highest $j \geq i$ for which that center is also a center in $\mathcal{C}_{j}$. For each vertex $w$ that has a neighbor $v$ already clustered in $\mathcal{C}_{i+1}, w$ declares $(w, v)$ to be a spanner edge (Rule R1) and declares its center in $\mathcal{C}_{i+1}$ to be that of $v$. Every vertex $w$ that did not become clustered in $\mathcal{C}_{i+1}$ declares one edge from $E(w, C)$ to be in the spanner (Rule R2), for each $C \in \mathcal{C}_{i}$ adjacent to $w$. Rules R1 and R2 require $k-1$ rounds of communication, plus one more to let clustered vertices in $\mathcal{C}_{k-1}$ inform their neighbors of this fact. Each message sent so far has unit length.

Once $\mathcal{C}_{0}, \ldots, \mathcal{C}_{k-1}$ are computed, we implement Rules R3 and R4. Consider Rule R3, a fixed $i \geq 0$, and a fixed cluster $C \in \mathcal{C}_{(k-1) / 2-i} \cdot{ }^{10}$ Rule R1 has created a tree $T$ of spanner edges rooted at the center of $C$. This tree is used to inform the center of $C$ of all incident clusters in $\mathcal{C}_{(k-1) / 2+i}$, and for each such cluster, one connecting edge. Once the center decides which edges to select for Rule R3 it broadcasts its choices back through $T$. The number of rounds for Rule R3 is clearly $O(k)$. The maximum necessary message length (for fixed $i$ ) is $\left|\mathcal{C}_{(k-1) / 2+i}\right|$ since duplicate edges connecting the same clusters can be ignored. With high probability $\left|\mathcal{C}_{(k-1) / 2+i}\right|=O\left(n^{1 / 2+1 / 2 k-i / k}\right)$. Summing over $i \geq 0$, the maximum message length is bounded by $O\left(n^{1 / 2+1 / 2 k}\right)$. For even $k, i$ is always at least $1 / 2$, so in this case the maximum message length is $O(\sqrt{n})$. The total message volume for Rule R3 is $O\left(k^{2} m\right)$ since each edge can participate for $k / 2$ values of $i$ and for each, contribute $O(k)$ units of message volume. The implementation and analysis of Rule R4 is very similar to R3.

## 4 Conclusion

The main existential question in the field of spanners is whether, for any given size bound $O\left(n^{1+\epsilon}\right)$, there exist additive $\beta(\epsilon)$-spanners and if not, which additive spanners do exist? For $\epsilon<1 / 3$ our additive spanners are the best known, but they have additive distortion that depends heavily on $n$. In this paper we introduced a general construction technique that might help to resolve the question of additive spanners for general graphs.

In Section 3 we addressed the problem of computationally efficient spanner constructions and gave partial answers to two problems of practical significance: what is the highest quality spanner that can be constructed in linear time? and which spanners can be constructed distributively in $O(1)$ rounds? It seems implausible that any additive or $(1+\epsilon, \beta)$-spanners admit such efficient constructions.

One promising direction for future research is to develop approximate distance oracles for unweighted graphs whose distortion improves with distance. The ultimate goal would be to have oracles with constant

[^6]additive distortion, though any improvement over the purely multiplicative distortion of $[54,13,43,11]$ would be a start. For example, there is no known $(3-\epsilon, \beta)$-distance oracle with size $O\left(n^{3 / 2}\right)$ whose query time is reasonably fast.

Acknowledgment. We would like to thank Uri Zwick, Mikkel Thorup, and Michael Elkin for some helpful comments on an earlier draft of this paper.

[^1]:    ${ }^{1}$ Girth is the length of the shortest cycle. Note that since every graph has a bipartite subgraph with at least half the edges, $\frac{1}{2} m_{2 k+1}(n) \leq m_{2 k+2}(n) \leq m_{2 k+1}(n)$.

[^2]:    ${ }^{2}$ Recall that $\left(S, \delta_{S}\right)$ is a metric if for $u, v, w \in S, \delta_{S}(u, u)=0, \delta_{S}(u, v)=\delta(v, u) \geq 0$, and $\delta_{S}(u, v) \leq \delta_{S}(u, w)+\delta_{S}(w, v)$.

[^3]:    ${ }^{3}$ For example, consider a cycle of $n$ vertices.
    ${ }^{4}$ They actually show this distortion holds for adjacent vertices, which is stronger.
    ${ }^{5}$ Notice the difference between absolute vs. relative distortion. Most results give an absolute guarantee on the distortion (perhaps in expectation) whereas [16] compare the distortion of their embedding against the optimal one. See [33, 31] for other (in)approximability results for different spanner problems.
    ${ }^{6}$ A metric has doubling dimension $d$ if the ball of radius $2 r$ centered at any point can be covered by $2^{d}$ balls of radius $r$.

[^4]:    ${ }^{7}$ This would be the exact probability if $V_{i}$ were selected from $V_{i-1}$ by sampling each element with probability $n^{-\epsilon}$. Selecting $V_{i}$ as a random subset of $V_{i-1}$ with size $n^{1-i \epsilon}$ only improves $v^{\prime}$ s chance of being clustered in $\mathcal{C}_{i}$.
    ${ }^{8}$ For the last inequality, observe that $s^{\prime}(1-1 / x)^{s^{\prime}} \leq x\left(s^{\prime} / x\right) e^{-s^{\prime} / x} \leq x$, for any positive $x$.

[^5]:    ${ }^{9}$ Recall that maximum distance between any two vertices in a subgraph is at most twice the radius of that subgraph.

[^6]:    ${ }^{10}$ If $k$ is odd then $i$ is an integer. For even $k, i$ is a half-integer.
